Yersinia pestis and Bubonic Plague

BOB BRUBAKER

Introduction

Caused by *Yersinia pestis*, bubonic plague (also known as “the pestilence” or “Black Death”) is the most devastating epidemic bacterial disease known to humankind. This appraisal is based upon the terrifying manifestations of plague (Butler, 1983; Pollitzer, 1954), which include death within 1–3 days following the onset of symptoms (Butler, 1983). Up to 200 million people have succumbed to this disease over the course of history (Duplais, 1988). On the other hand, the closely related *Yersinia pseudotuberculosis* or the more divergent *Yersinia enterocolitica* (termed “enteropathogenic” yersiniae because they typically produce gastrointestinal afflictions) do not have the ability of plague bacilli to cause comparable acute lethal disease in rodents and primates. Nevertheless, these three human parasites exhibit a similar basic pattern of pathogenicity mediated by a shared ~70-kb plasmid termed “pCD” in *Y. pestis*, “pYV,” “pCad” or “pIB” in *Y. pseudotuberculosis*, and “pYV” in *Y. enterocolitica* (Ben-Gurion and Shafferman, 1981; Cornelis and Wolf-Watz, 1997; Ferber and Brubaker, 1981; Goguen et al., 1984; Hu et al., 1998; Iriarte and Cornelis, 1996; Perry and Fetherston, 1997; Perry et al., 1998). Hereafter, the term pCD will apply to the ~70-kb plasmid of *Y. pestis* and pYV will designate its analog in both *Y. pseudotuberculosis* and *Y. enterocolitica*. Cells of wild-type *Y. pestis*, most but not all serotypes of *Y. pseudotuberculosis*, and invasive isolates of *Y. enterocolitica* also possess an ~35-kb chromosomally encoded high-pathogenicity island (Bearden et al., 1997; Buchrieser et al., 1998a; Buchrieser et al., 1998b; Buchrieser et al., 1999; Carniel et al., 1996; Fetherston et al., 1995; Fetherston and Perry, 1994; Fetherston et al., 1992). The shared plasmid encodes a battery of cytotoxins termed “Yops” and at least three anti-inflammatory activities, whereas the high-pathogenicity island contains genes required for the siderophore (yersiniabactin)-dependent assimilation of iron. Superimposed on this common theme are two unique plasmids in *Y. pestis* that facilitate invasion of tissues and colonization of the flea vector. In addition, plague bacilli have

lost central enzymes of intermediary metabolism and host cell adhesin and invasin activities required by the enteropathogenic yersiniae to express chronic infection (Achtman et al., 1999; Brubaker, 1991; Brubaker, 2000; Hinnebusch, 1997). As a consequence of this genomic fine-tuning, plague has become the yardstick by which all other acute infectious diseases are measured. *Yersinia pestis* is now more firmly entrenched in endemic foci throughout the world than at any previous time (Baltazard, 1960; Perry and Fetherston, 1997). Although controllable by antibiotics, the emergence of drug-resistant isolates has been reported (Galimand et al., 1997). The probability of acquiring the disease from natural reservoirs (sylvatic plague) will increase as the human population continues to press into endemic regions. Finally, the possibility that *Y. pestis* will be utilized as an agent of terrorism is sobering. Accordingly, it is imperative to fully understand the molecular workings of this formidable pathogen so that alternative strategies to antibiotic therapy can be developed to combat the probable recrudescence of plague in humans.

Considerable progress toward a better understanding of the shared features of plague and the chronic diseases caused by the enteropathogenic yersiniae recently has been made. From the discovery of *Y. pestis* in Hong Kong by Alexander Yersin in 1896 until well into the 1980s, the symptoms of plague were generally viewed as the consequence of a relentless and uncompromising conflict between host and parasite (Brubaker, 1972; Burrows, 1963; Butler, 1983; Pollitzer, 1954). However, results of later experiments indicate that these symptoms more accurately reflect the combination of stealth and deception effects, which cause the host to ignore the mortal danger of ongoing systemic invasion. In this context, the “stealth” refers to the ability of docked yersiniae to translocate cytotoxins directly into host cell cytoplasm via a type III protein secretion system (Michiels et al., 1990), thereby effectively bypassing the immune system. Similarly, use of the word “deception” characterizes the capacity of *Y. pestis* to suppress inflammation by downregulating proinflammatory cytokines (Nakajima and Brubaker, 1993). Both of these

mechanisms, as well as ancillary activities required for growth in vivo and invasion of tissues, have undergone intensive recent study and are considered under Disease.

As already noted, an interesting feature of *Y. pestis* is its remarkably close homology to *Y. pseudotuberculosis* (Brenner et al., 1976; Moore and Brubaker, 1975), an organism capable of causing chronic disease in a variety of mammals and birds. *Yersinia pseudotuberculosis* has long been recognized as the immediate forebear of *Y. pestis*, and analysis of restriction enzyme fragment polymorphism place the occurrence of divergence just 1,500 to 20,000 years ago (Achtman et al., 1999). The close genetic relationship between these two species and the dramatic differences in symptoms of plague versus human pseudotuberculosis thus provide a unique model for defining the nature of acute disease. As might be expected, differences between the genomes of these yersiniae are modest; they comprise the acquisition by *Y. pestis* of two unique plasmids and loss of chromosomal genes that, in *Y. pseudotuberculosis*, facilitate expression of enteropathogenic disease and efficient intermediary metabolism. Nevertheless, these differences cause marked phenotypic distinctions, which are defined under Physiology. The putative sequence of events and selective pressures favoring the emergence of *Y. pestis* from *Y. pseudotuberculosis* are considered under Phylogeny.

Overviews of *Y. pestis* and its virulence factors are available (Brubaker, 1991; Brubaker, 2000; Perry and Fetherston, 1997) as are descriptions of the disease (Bahmanyar and Cavanaugh, 1976; Poland and Barnes, 1979; Pollitzer, 1954); the book by Thomas Butler provides an especially vivid picture of plague (Butler, 1983). The important role of the shared -70-kb plasmid with emphasis on the translocation of virulence effectors via a type III mechanism of protein secretion has been reviewed in detail (Cornelis, 1998a; Cornelis, 1994; Cornelis, 1992; Cornelis et al., 1998b; Cornelis and Wolf-Watz, 1997).

Phylogeny

As noted in the Introduction, *Y. pestis* is a recently evolved clone of *Y. pseudotuberculosis* (Achtman et al., 1999). The close relationship between these species provides an excellent model for defining the nature of acute systemic disease (typified by plague) as opposed to the chronic and localized lymphadenitis and gastroenteritis usually caused by *Y. pseudotuberculosis* (Daniels, 1973). The remarkably small number of phenotypic differences known to exist between the two species (Table 1) has prompted speculation as to the nature of hereditary changes

required for expression of acute disease and the order of their occurrence (Achtman et al., 1999; Brubaker, 1991; Brubaker, 2000; Hinnebusch, 1997). Tacit to all models of emergence is recognition that cells of *Y. pestis* have both gained new genetic information not shared by *Y. pseudotuberculosis* and lost functions that its progenitor has retained.

Unique traits of *Y. pestis* known to mediate the acute symptoms of plague are defined under Disease; they consist of pPCP-encoded plasminogen activator (Pla) plus pMT-encoded capsular fraction 1 antigen (Caf1) and murine toxin. Chromosomally encoded virulence functions particular to *Y. pestis* have not been established as yet but certainly may exist. The present extrachromosomal existence of the structural genes encoding Pla, Caf1 and murine toxin strongly suggests their recent acquisition by lateral transfer, despite the fact that neither pPCP nor pMT exhibit sex-factor activity (Hu et al., 1998; Lindler et al., 1998). This deficiency is inconsequential in the case of pPCP, which is sufficiently small (9.7 kb) to readily co-conjugate with the sex factor F (Kutyrev et al., 1999). However, larger plasmids (such as pMT, 100.9 kb) might not be expected to undergo lateral transfer in nature via co-conjugation or transformation, although transfer by transformation can be accomplished in the laboratory. The *raison d'être* of plasmids is to provide the host bacterium with some novel or unique capability to facilitate survival in an otherwise hostile environment. The plasmid pMT is an enigma in this sense in that it encodes not only structural genes for Caf1 and murine toxin (thereby providing the requisite selective advantage), but also genes for a number of plebeian functions probably concerned with normal vegetative growth (Hu et al., 1998; Lindler et al., 1998). Two additional findings emphasize this conundrum. First, pMT, in its entirety, can readily integrate into the chromosome (Protsenko et al., 1991). Second, the -18-kb operon of pMT encoding the structural gene for Caf1 (*caf1*) and attendant functions is linked to bacteriophage homologs and possesses a distinct guanine plus cytosine (G+C) content; pMT may thus exist as a second high-pathogenicity island (Hu et al., 1998; Lindler et al., 1998). These observations are consistent with the notion that the genes encoding Caf1 and murine toxin may now reside in locations different from those first entered in the genome.

In accord with the prospect of a flexible genome is the important discovery by Portnoy and Falkow (1981a) that up to 30 copies of the insertion sequence (IS) element IS100 exist within the chromosome of *Y. pestis*, as well as at least one copy within each plasmid. This element was sequenced (Podladchikova et al., 1994) and

Table 1. Phenotypic distinctions between typical strains of *Y. pestis* and *Y. pseudotuberculosis*.

Determinant	<i>Y. pestis</i>	<i>Y. pseudotuberculosis</i>	Mutational event	Consequence in <i>Y. pestis</i> ^a	References
pPCP	+	0	Lateral transfer	Acquisition of plasminogen activator (accelerated dissemination in host tissues and posttranslational degradation of undelivered Yops) Acquisition of pesticin (assures retention of pPCP)	Ben-Gurion and Shafferman, 1981 Ferber and Brubaker, 1981 Protsenko et al., 1983
pMT	+	0	Lateral transfer	Acquisition of capsular fraction 1 antigen (resistance to phagocytosis) Acquisition of murine toxin (survival in the flea vector and prompt death of murine hosts)	Kutyrev et al., 1986 Protsenko et al., 1983 Protsenko et al., 1991

Assimilation of low levels of NH ₄ ⁺ into organic linkage	0 ^b	+	Possible loss of glutamine synthase by unknown mutational event	Elimination of unnecessary function	Brubaker and Sulen, 1971

Abbreviations: pPCP, pesticin-producing plasmid; +, present; 0, absent; Yops, yersinia outer proteins; pMT, metallothionein plasmid; Pgm, pigmentation phenotype; *hms*, hemin storage locus; YadA, yersinia adhesin phenotype; Inv, a host cell invasin; Ail, another host cell invasin.

^aThese issues are considered further in sections concerned with Phylogeny, Physiology, and Disease.

^bKnown to undergo meiotrophic reversion to the *Y. pseudotuberculosis* phenotype.

further work revealed the presence of additional IS285 (Filippov et al., 1995) and IS200-like (Simonet et al., 1996) inserts. At least 15 copies of the latter, now termed "IS1541," exist in the chromosome (Odaert et al., 1998; Simonet et al., 1996). Recognition of these elements in *Y. pestis* initially prompted the specter of chromosomal instability due to the occurrence of continuous insertion and excision. However, many of the inserts lack inverted terminal repeats, and it is now believed that some, if not all, are immobile (Odaert et al., 1998). Nevertheless, their widespread distribution within the genome has important consequences. One such outcome is that their existence, especially in close proximity, can result in reciprocal recombination accompanied by loss of intervening DNA. This situation was observed first by Fetherston et al. (1992) for the high-frequency deletion of the pigmentation (*pgm*) locus (Brubaker, 1970a). As defined under Physiology, this 102-kb deletable sequence contains a ~35-kb high-pathogenicity island encoding functions required for synthesis of the siderophore yersiniabactin and a linked ~6-kb hemin storage (*hms*) locus necessary for blocking the flea proventriculus. In nature, deletion of this region obviously is lethal to *Y. pestis*. However, analogous but nonlethal recombinational events between IS elements conceivably may have occurred during the evolution of the species, resulting in the formation of large chromosomal inversions or transpositions without net loss of DNA. Indeed, reciprocal recombination between IS elements may account for the observed integration and excision of plasmids. A comparison of the order of genes in fully sequenced chromosomes of *Y. pestis* and *Y. pseudotuberculosis* will be instrumental in determining the role, if any, played by internal chromosomal rearrangement in the emergence of plague.

Of possible additional importance in the expression of acute disease is the generation of mutations as a direct consequence of IS insertion within the chromosome. The total genome of *Y. pestis* is 4,389.5 kb as judged by two-dimensional pulsed-field gel electrophoresis (Lucier and Brubaker, 1992). Assuming an approximate length of 700 bp for each of the ~50 inserts present in the species, it is evident that almost 0.1% of the genome is composed of these elements. The sequence of sites preferred for insertion is not fully resolved but convincing evidence has accrued indicating that IS1541 may prefer stem-loop structures resembling θ -independent transcription terminators (Odaert et al., 1998). Genes in *Y. pestis* known or suspected to have undergone inactivation by IS elements resulting in identified changes of phenotype are noted in Table 1. Two of these encode the host cell inva-

sins *Inv* and *Ail*, which are established important virulence factors of the enteropathogenic yersiniae (Finlay and Falkow, 1997). Aspartase also may have undergone inactivation by insertion. Disruption by IS elements is not, of course, the only mechanism that caused loss of structural genes during the emergence of *Y. pestis*. An alternative process is the occurrence of errors in DNA replication evidenced by addition or deletion of bases or sequences within runs of the same base or sequence. Examples of these frameshift mutations are loss of the ability to express chromosomally encoded urease (Sebbane et al., 1999) and *YadA*, which are encoded is a pseudogene on pCD (Rosqvist et al., 1988). Like *Inv* and *Ail*, *YadA* is an important virulence factor required by enteropathogenic yersiniae for gastrointestinal invasion (Finlay and Falkow, 1997; Ruckdeschel et al., 1996). A similar but phenotypically undefined event is the mutation to *YlpA*⁻, also encoded as a pseudogene on pCD (Hu et al., 1998; Perry et al., 1998).

It is not yet certain whether the mutations listed in Table 1 occurred by accident or design. That is, was a determinant so dispensable that its random loss in an early clone did not reduce fitness or was its removal from the genome to provide a selective advantage? Probably both mechanisms were at work during the emergence of *Y. pestis*. For example, it is difficult to imagine how the ability to ferment an uncommon sugar (such as rhamnose or melibiose) would assist an organism restricted to an environment (the nutritionally rich mammalian host or flea vector) probably lacking significant levels of these carbohydrates. Nevertheless, these traits might benefit an enteropathogenic species, when between hosts, to compete with saprophytes in austere natural environments for lengthy periods. The same argument holds for the ability to assimilate low levels of NH_4^+ , hydrolyze urea or synthesize amino acids. All of these properties favor maintenance in soil or water but are redundant in host fluids or the gorged flea vector. Indeed, pioneer studies undertaken with *Y. pestis* designed to correlate auxotrophy and avirulence demonstrated that the ability to synthesize many amino acids, pyrimidines and vitamins is dispensable, and only nutritional dependence on exogenous purines prevents sustained growth in vivo (Burrows, 1960; Burrows, 1963; Burrows and Gillett, 1966). On the other hand, loss of other traits shared by *Y. pseudotuberculosis* and *Y. enterocolitica* might facilitate the rapid invasion of tissues characteristic of plague bacilli. For example, the determinants *YadA*, *Inv* and *Ail* promote penetration of the intestinal tract by the enteropathogenic yersiniae and, as such, serve as host cell adhesins (Finlay and Falkow, 1997). These activities, however, would become unnec-

essary, if not a liability, upon acquisition of the pPCP-encoded ability of Pla to initiate an intradermal or subcutaneous infection following administration by fleabite. That is, selective pressure favoring the ability of Pla to promote rapid dissemination to visceral organs, known to serve as favored niches for vegetative growth (Nakajima et al., 1995; Straley and Cibull, 1989; Une and Brubaker, 1984a; Une and Brubaker, 1984b; Une et al., 1986), would reward mutational loss of YadA, Inv and Ail. In this context, it is significant that loss of YadA in *Y. pseudotuberculosis* was reported to increase virulence (Rosqvist et al., 1988) as might be expected if YadA inhibited bacterial dissemination in tissues. Unfortunately, these results could not be repeated (Han and Miller, 1997), but further study may show that introduction of YadA into *Y. pestis* can reduce infectivity.

The advantage of removing adhesins that would otherwise serve as anchors impeding tissue invasion is readily understood. In contrast, the prospect that elimination of enzymes central to intermediary metabolism (such as glucose 6-phosphate dehydrogenase or aspartase) also might favor the occurrence of acute disease is more subtle. These enzymes are central to efficient intermediary metabolism in complex enriched media. For example, loss of glucose 6-phosphate dehydrogenase blocks the hexose monophosphate pathway, thereby favoring the assimilation of gluconate or ribose in vivo (Mortlock, 1962a; Mortlock and Brubaker, 1962b). Interconvertible tricarboxylic acid cycle intermediates are lost as excreted aspartate in aspartase-deficient *Y. pestis* (Dreyfus and Brubaker, 1978), which accounts, in part, for the increased doubling time and reduced terminal population of *Y. pestis* grown in vitro as compared with *Y. pseudotuberculosis*. However, the fact that these enzymatic deficiencies are deleterious to *Y. pestis* in vitro by no means indicates that their mutational losses similarly reduce fitness in vivo. The consequences of the absence of glucose 6-phosphate dehydrogenase and aspartase in *Y. pestis* are considered in greater detail under Physiology and Disease.

It is of considerable historical interest that many, but not all, of the traits expressed by *Y. pseudotuberculosis*, but not *Y. pestis*, can be recovered by use of appropriate selective media. This phenomenon was first demonstrated by Englesberg (1957a), who isolated rare mutants (termed "meiotrophs") capable of fermenting rhamnose from otherwise typical cells of *Y. pestis*. Results of similar studies showed that other traits generally absent in *Y. pestis* including urease, and the ability to assimilate low levels of NH_4^+ , synthesize certain amino acids, and ferment melibiose (Table 1) also could be restored

by meiotrophic reversion (Brubaker and Sulen, 1971; Englesberg and Ingraham, 1957b). It may be significant that all of these cases involve loss of a chromosomally encoded gene not essential for growth in either the flea vector or mammalian host. As already noted, loss of urease involves a single base deletion (Sebbane et al., 1999) typical of rare mutations in DNA replication. This type of forward mutation can readily undergo true reversion; inspection of the sequenced genome may reveal that the loss of other nonessential traits subject to meiotrophic reversion reflects similar occurrence of uncommon errors in replication.

Isolates of many but not all serotypes of *Y. pseudotuberculosis* also possess the high-pathogenicity island encoding yersiniabactin, although their location in the chromosome differs from that in *Y. pestis* (Buchrieser et al., 1998a; Buchrieser et al., 1999; Hare et al., 1999b). Likewise, DNA of *Y. pseudotuberculosis* contains IS elements identical to those of *Y. pestis*, although the number of total copies is considerably smaller (Devalckenaere et al., 1999; Hare et al., 1999b; Odaert et al., 1996). Based on this information and that provided previously, the following scenario may define the emergence of *Y. pestis*. First, a clone of *Y. pseudotuberculosis* capable of yersiniabactin synthesis and hemin absorption procured CafI and murine toxin presently encoded by pMT. It is understood that this addition need not necessitate direct transformation of pMT per se but could involve acquisition of the two determinants by other, perhaps even independent, steps. Supporting this notion is the observation that the operon mediating expression of CafI is an evident high-pathogenicity island replete with flanking bacteriophage homologs (Hu et al., 1998; Lindler et al., 1998). Acquisition of CafI and especially murine toxin, which are known to facilitate survival of yersiniae within the flea midgut (Hinnebusch et al., 1998a; Hinnebusch et al., 1999), would irreversibly change the hereditary destiny of *Y. pseudotuberculosis* by providing a new selective pressure leading inevitably to the emergence of lethal disease. These influences are threefold. First, the recipient early clone would become protected within a closed flea-host-flea cycle and thus be released from the necessity of competing with saprophytes in natural environments. Accordingly, mutational loss of traits that favor survival in austere environments could occur with impunity. Second, the transformed bacterium would become dependent upon the flea for transfer to new hosts and therefore subsequent genetic changes that favor death of the old host would provide a selective advantage. Third, expression of the Hms⁺ phenotype, known to be potentially detrimental in vitro (Brubaker,

1970b), now could become constitutive at 26°C, thereby, furthering fitness within the flea.

The newly evolved mechanism of bacterial transfer by fleabite rewarded later mutational events favoring acute disease because death assures that resident fleas will disembark in search of new hosts. This strategy, of course, is distinct from that of *Y. pseudotuberculosis* where expression of a chronic enteropathogenic infection favors prolonged and extensive release of bacteria into natural environments. In this context, it is significant that mice infected intravenously with *Y. pestis* succumb to infection earlier and exhibit a lower bacterial burden in visceral organs than do mice similarly infected with *Y. pseudotuberculosis* (Nakajima et al., 1995; Une and Brubaker, 1984a). The acquisition of pPCP-encoded Pla, known to facilitate tissue invasion (Brubaker et al., 1965; Lahteenmaki et al., 1998; Sodeinde et al., 1992), probably occurred after establishment of the flea-host-flea cycle as did mutational loss of *YadA*, *Inv* and *Ail*, which were previously required by the *Y. pseudotuberculosis* parent for penetration and colonization of the host gastrointestinal tract. These determinants were no longer essential for invading the viscera, which now was readily accessed following infection by fleabite via the action of Pla. Indeed, the three activities possibly restricted the Pla-dependent process now utilized by the emerging plague bacillus for dissemination from peripheral sites of infection to the viscera. Furthermore, *YadA*, *Inv* and *Ail* all promote intimate association with both professional and nonprofessional phagocytes, a process that would be expected to upregulate proinflammatory cytokines, thereby alerting the host to the advent of systemic disease. As noted under Disease, the hallmark of plague is downregulation of IFN- γ and TNF- α (Nakajima and Brubaker, 1993); thus, loss of factors capable of upregulating expression of these and other proinflammatory cytokines would become favored. Further work will be required to determine if elimination of glucose 6-phosphate dehydrogenase and of aspartase also contributes to expression of acute disease. As noted under Physiology, removal of these activities might very well alter the local amino acid pools of the host, thereby actually increasing the efficiency of catabolism *in vivo*.

Evident early endemic forms of *Y. pestis* remain in the ancient plague reservoirs of Russia. These "Pestoides" isolates differ from the epidemic forms of the species in that pPCP is not required for tissue invasion (Samoilova et al., 1996; Welkos et al., 1997). A definitive comparison of the genome of these isolates to those of *Y. pseudotuberculosis* and typical epidemic forms of *Y. pestis* may help in unraveling the evolutionary pathway to plague. In summary, the

epidemic form of *Y. pestis* now resident in sylvatic foci throughout the world has evolved as a rare exception to the epidemiological tenet of Theobald Smith (Smith, 1934). This principle states in essence that it is ruinous strategy for a parasite to seriously debilitate its host because, by so doing, that parasite threatens the only environment capable of supporting its own existence in nature. Smith's premise clearly applies to the enteropathogenic yersiniae where maintenance of a chronic low-grade infection favors transmission of the agents to new hosts via fecal contamination. However, acquisition of a more certain route of transfer (i.e., fleabite) mediated by the *hms* locus (Hinnebusch et al., 1996) and pMT (Hinnebusch et al., 1998b; Hinnebusch et al., 1999) favored selection for lethality because death is required to assure the departure of the vector in search of a new host. Once this mechanism of transfer became fixed, additional hereditary changes such as acquisition of pPCP and loss of *YadA*, *Inv* and *Ail* provided increased fitness, which facilitated emergence of the most destructive epidemic disease experienced by humankind. This concept is cavalier in that it ignores the prospect that the high-pathogenicity island encoding yersiniabactin synthesis has evidently undergone transfer to yersiniae on separate occasions (Buchrieser et al., 1998a; Hare et al., 1999b). It further overlooks the finding that the bacteriocin pesticin, also encoded on pPCP (Ferber and Brubaker, 1981), utilizes as a target the yersiniabactin-receptor *Psn* encoded within the high-pathogenicity island (Fetherston et al., 1995; Fetherston and Perry, 1994; Lucier et al., 1996; Rakin et al., 1996; Sikkema and Brubaker, 1987) suggesting prior association between *psn*, linked *pla*, and the chromosomally encoded high-pathogenicity island. The scenario only peripherally addresses the possibility that known changes in intermediary metabolism caused by loss of glucose 6-phosphate dehydrogenase and of aspartase contribute to the severity of disease. Finally, the ability of Pestoides variants to undertake Pla-independent invasion of tissues is overlooked. Again, direct comparison of the fully sequenced genomes of *Y. pestis* and *Y. pseudotuberculosis* should resolve the nature and order of genetic changes accounting for the emergence of plague. Divergence of *Y. pestis* has continued after its emergence; properties used to distinguish biovars of the species are discussed under Epidemiology.

Taxonomy

Yersinia (constituting Genus XI of the Family Enterobacteriaceae) includes *Y. pestis* as the type species, enteropathogenic *Y. pseudotuber-*

culosis and *Y. enterocolitica*, *Y. ruckeri* (a primary pathogen of fish), and secondary invaders or saprophytes (*Y. aldovae*, *Y. bercovieri*, *Y. frederiksenii*, *Y. intermedia*, *Y. kristensenii*, *Y. mollar-etii* and *Y. rohdei*). Only the first three listed species share pCD/pYV required for expression of primary disease in mammals (Brubaker, 2000; Perry and Fetherston, 1997). Both *Y. pestis* and *Y. pseudotuberculosis* exhibit a 46 to 47 mol% G+C content as opposed to values of 47 to 48.5 established for DNA of *Y. enterocolitica*. Under stringent conditions of reassociation, DNA of *Y. pestis* exhibited 9, 23 and 83% homology to that of *Escherichia coli*, *Y. enterocolitica* and *Y. pseudotuberculosis*, respectively; hybridization with tested species classified outside of the Enterobacteriaceae was not significant (Moore and Brubaker, 1975). The hybridization of DNA under more permissive conditions and biochemical characterization by Dr. H. H. Mollaret and colleagues at the Institut Pasteur, Paris, verified this relationship and provided the basis for defining the additional eight species of the genus (Bercovier et al., 1980; Brenner et al., 1976). Determinations of restriction fragment length polymorphism by Achtman et al. (1999) indicated that *Y. pestis* diverged from *Y. pseudotuberculosis* only 1,500 to 20,000 years ago but that their progenitor separated from *Y. enterocolitica* at least 41 million years earlier. The similarity in gene order between pCD and pYV of *Y. pseudotuberculosis* as opposed to that of pYV from *Y. enterocolitica* (Hu et al., 1998) further substantiates the close relationship between *Y. pestis* and *Y. pseudotuberculosis*. As judged by analysis of 16S rRNA, the genus provides a coherent cluster where *Y. pestis*, *Y. pseudotuberculosis* and certain isolates of *Y. kristensenii* represent one subline, and *Y. enterocolitica* forms another (Ibrahim et al., 1993).

Habitat

The two major environments exploited by *Y. pestis* in nature consist of the flea vector and the mammalian host. At least two genetic elements (the chromosomally encoded *hms* locus and pMT) are required for growth of plague bacilli in the flea proventriculus. On the other hand, full virulence in rodents requires carriage of pCD, pPCP, pMT, a chromosomal high-pathogenicity island, and a modest number of additional chromosomal genes shared by *Y. pseudotuberculosis* (Achtman et al., 1999; Brubaker, 1991; Brubaker, 2000; Perry and Fetherston, 1997). Functions required for survival in these niches and their regulation are described under Physiology; the effect of virulence factors on the host is defined in Disease. As noted under Phylogeny,

the ability to thrive in both the flea vector at room temperature and host at 37°C probably reflects lateral transfer of extrachromosomal elements during the recent evolution of the species. Plague bacilli also have been isolated from soil recovered from the depths of burrows of social rodents recently exterminated by the disease (Bahmanyar and Cavanaugh, 1976). Whereas the ability to survive in this circumstance may facilitate infection of new occupants, plague bacilli are poorly equipped for competition with saprophytes and rapidly disappear from most natural environments (Poland and Barnes, 1979).

Isolation

During the course of epizootics, cells of *Y. pestis* can readily be isolated in essentially pure culture from tissues or fluids obtained from the moribund or recently deceased rodent host. In this situation, tissue from the liver or spleen, as well as blood from the heart, typically contain large numbers of yersiniae and are favored sources for subculture. Material aspirated directly from buboes of human patients also is rich in plague bacilli as is sputum obtained from victims of the pneumonic form of the disease. The organisms also have been isolated from fleas removed from rodents captured in epizootic foci. One technique used to facilitate this process is to stun the fleas present on a captured host by brief exposure to chloroform vapor and then macerate these vectors with a sterile glass rod. The resulting debris can then be enriched by inoculation into mice or even streaked directly onto the surface of any of a number of solid enriched commercial media and incubated at room temperature for 2 days. Blood agar base or heart infusion agar is often used for routine isolation and cultivation of *Y. pestis* and the enteropathogenic yersiniae. All of the above sources can yield confluent growth on solid media at the initial site of inoculation; bacteria isolated in pure culture from single colonies should be subcultured at room temperature to avoid possible population shifts accompanied by avirulence caused by loss of pCD. Detailed information is available for epidemiologists and clinicians concerned with primary isolation of *Y. pestis* in the field (Bahmanyar and Cavanaugh, 1976; Butler, 1983; Poland and Barnes, 1979; Pollitzer, 1954).

Identification

Identification of *Y. pestis* is undertaken at three levels depending upon urgency and the nature of determinative reagents that are on hand. Level one concerns tentative identification in the field;

level two is verification of the preliminary determination with a specific immunological assay; and level three involves use of modern, highly sensitive procedures involving specific molecular probes. The first case of an outbreak is typically the most difficult but most important one to recognize. Unfortunately, clinicians in rural areas where the disease is not anticipated often lack specific reagents necessary for making a correct diagnosis. In this situation, it is imperative that the possibility of plague be considered if a patient has a fever accompanied by a swollen and tender regional lymph node (bubo) or bloody sputum. In the case of plague, fluid recovered from these sources typically contains numerous bacteria visible in direct smears as small stout Gram-negative rods. This material can be used to isolate the organisms on solid medium, tested directly by fluorescent antibodies, or prepared for analysis with specific antigen or oligonucleotide probes. Epidemiologists and public health workers utilize pooled flea detritus as a favored source of yersiniae; this material can be enriched by injection into mice.

In almost all cases, positive identification of *Y. pestis* is dependent upon recognition of at least one of the unique determinants listed in Table 1. A formal determination of *Y. pestis* or diagnosis of plague is dependent upon demonstrating specific genes or gene products. Nevertheless, clinicians lacking specific reagents can still provide convincing evidence that suggests a suspicious organism is indeed *Y. pestis*. Isolates falling into this category should be forwarded to a regional public health facility in possession of specific reagents for further analysis and verification.

Properties used to characterize yersiniae in the field are discussed under Phylogeny and Physiology; their determinative potential was defined by Surgalla et al. (1970). These factors are the abilities of *Y. pestis* to grow as Pgm⁺ colonies at 26°C on hemin (Jackson and Burrows, 1956a) or Congo red agar (Hare and McDonough, 1999a; Surgalla and Beesley, 1969), elaborate Pla as judged by use of fibrin plates or rabbit plasma (Beesley et al., 1967), produce the bacteriocin pesticin capable of killing serotype IA or IB cells of *Y. pseudotuberculosis* on solid medium (Brubaker and Surgalla, 1961), and exhibit a -10^4 -fold reduction in ability to form colonies on magnesium oxalate agar at 37°C as opposed to 26°C (Higuchi and Smith, 1961). The obvious disadvantage of these methods is they depend upon prior isolation of the bacteria in pure culture, although hemin or Congo red agar may be used for this purpose. Indeed, any Gram-negative rod recovered from a patient exhibiting clinical symptoms suggestive of plague (as defined under Disease) should be suspected of being *Y. pestis*, if the isolate requires 2 days to

form visible pigmented colonies. Further demonstration of fibrinolytic activity (or coagulation of rabbit plasma), a temperature-dependent differential in ability to form colonies on magnesium oxalate agar, and inhibition of *Y. pseudotuberculosis* in an agar overlayer strongly suggests that the isolate is *Y. pestis* (Surgalla et al., 1970). Another novel test for *Y. pestis* is constitutive expression of isocitrate lyase, a component of the glyoxylate bypass (Quan et al., 1982). Those Pgm⁺ isolates possessing any of the additional properties noted above should be handled with caution and are worthy of submission to a central laboratory capable of specific diagnosis.

Clinical specimens suspected of containing *Y. pestis* can be determined immediately in regional health facilities by use of a standardized fluorescent antibody procedure dependent upon detection of capsular Caf1; this and other serological techniques (including the widely used passive hemagglutination test) are described by Butler (1983). The latter also is dependent on expression of Caf1 and has traditionally been used to verify diagnosis of the organism; this procedure is still viewed by many workers as the gold standard for diagnosis of plague. However, a number of more sensitive molecular determinations based on the use of specific antigen (Butler, 1983) or oligonucleotide probes have recently been developed. Extremely sensitive methods that utilize oligonucleotide targets to unique determinants are now used in many public health centers routinely to screen clinical specimens received from the field. Paramount in this effort was the use of polymerase chain reaction (PCR) for amplification of DNA sequences capable of interacting with probes prepared from *pla*, *caf1* or both (Campbell et al., 1993; Hinnebusch and Schwan, 1993; Norkina et al., 1993; Tsukano et al., 1996). Another such method that does not rely on unique structural genes is the procedure of Trebesius et al. (1998), which depends upon amplification of a 23S rRNA sequence specific to *Y. pestis*. This technology successfully identified sequences of *pla* and *Y. pestis*-specific *rpoB* (β -subunit of RNA polymerase) in ancient DNA recovered from dental pulp of plague victims of the second pandemic in France (Drancourt et al., 1998). Detection in fleas using PCR proved superior to inoculating mice (Engelthaler et al., 1999). Indeed, a Q-PCR procedure designed to detect *pla* provided valuable information regarding the distribution of blocked versus merely infected fleas in the aftermath of a naturally occurring epizootic (Hinnebusch et al., 1998a). Second generation procedures designed to ascertain hybridization of specific probes have increased the sensitivity of detection. For example, use of a fluorescently labeled oligonucleotide probe to determine Pla via “TaqMan”

technology permitted specific detection of 210,000 copies of the target (1.6 pg of bacterial DNA) in clinical samples (Higgins et al., 1998). Similarly, use of a branched-chain DNA assay to detect *pla* in concert with an enzyme-linked immunosorbent assay (ELISA) and light addressable potentiometric sensor formats yielded detection limits of 10,000 and 1,000 targets, respectively (Iqbal et al., 1999).

Although *Pla* is clearly specific for *Y. pestis*, it is a close analog of *OmpT* of *E. coli* (Sodeinde and Goguen, 1989), an outer membrane protein shared by many enteric bacteria. Accordingly, sequences must be chosen carefully when designing a probe that can specifically recognize *pla*. The bacteriocin *pesticin*, also encoded on *pPCP* (but by *pst*), was not shared by other tested bacteria (Vollmer et al., 1997); thus, it may prove to be a superior specific target. This prospect was supported by the finding that only 3 copies of *pst* targets were sufficient to yield a positive reaction by *TaqMan* analysis (Iqbal et al., 2000). Unlike results obtained with *pla* targets (Higgins et al., 1998), those reported for *pst* targets were not influenced by thermal cycle number, suggesting that *pesticin* is very specific for *Y. pestis* (Iqbal et al., 2000).

Cultivation

Plague bacilli can multiply between pH 5.5 to 9.0 at temperatures ranging from about 4 to 42°C; doubling times are markedly decreased by aeration. The effect of temperature on the nutrition and phenotype of *Y. pestis* is remarkable and undoubtedly reflects distinct adaptations favoring survival in the flea vector and host. The bacteria are robust during growth at -26°C and capable of achieving extraordinarily high terminal populations in enriched media (Higuchi and Carlin, 1957). The organisms exhibit a nutritional requirement at 26°C for sulfite, thiosulfate, or L-cysteine as a source of sulfur (Englesberg and Ingraham, 1957b) plus exogenous L-threonine (replaceable by glycine), L-methionine, L-isoleucine, L-valine and L-phenylalanine (Brubaker and Sulen, 1971; Burrows and Gillett, 1966). The need for L-isoleucine, L-valine and L-phenylalanine is not absolute and examination of the sequenced genome may reveal that these lesions reflect loss of regulatory functions. The addition of one of the three sources of sulfur also provides reducing potential that favors colony formation on solid medium; sodium thiosulfate (2.5 mM) is often used for this purpose, although hemin also may be employed (Herbert, 1949). The organisms evidently cannot assimilate low levels of NH_4^+ into organic linkage (Brubaker and Sulen, 1971), thus the addition of this cation

to minimal medium at concentrations of 10 mM is recommended. Growth also depends upon a source of fermentable carbohydrate. Although readily metabolized, D-glucose is not suitable for this purpose due to its prompt conversion to organic acids, causing marked reduction of pH. This difficulty is avoided by use of D-gluconate (Brubaker and Surgalla, 1964; Mortlock, 1962a), which is tolerated at concentrations of at least 0.04 M and maintains neutrality throughout logarithmic growth (Fowler and Brubaker, 1994). Consequently, a minimal medium for *Y. pestis* might contain physiological salts (K^+ , Mg^{2+} , Mn^{2+} , Fe^{3+} and HPO_4^{2-}), NH_4^+ as a source of nitrogen, D-gluconate as a source of carbon and energy, thiosulfate as a source of sulfur and reducing agent, and substrate levels of L-threonine, L-isoleucine, L-valine, L-methionine and L-phenylalanine (Brubaker, 1970a; Brubaker and Sulen, 1971). Growth at 26°C or less (especially in enriched media) may result in aggregation and adherence of *Pgm*⁺ *yersiniae* to the surface of culture vessels eventually causing emergence of an even suspension composed of avirulent *Pgm*⁺ mutants.

Cultivation at 37°C in chemically defined media is far more exacting and requires the presence of additional nutrients. Media constructed to mimic the composition of mammalian cytoplasm are generally satisfactory for this purpose, although absolute nutritional requirements for amino acids other than those needed for growth at 26°C are difficult to establish. Problems in defining requirements for additional nutrients at host temperature largely stem from the inadvertent introduction of unbalanced or toxic conditions caused by removal of single components. In addition, the possibility exists that functions concerned with vegetative growth at 26°C, especially active transport, are downregulated at 37°C. For many purposes, it is possible to use commercial preparations of natural products such as casein digests or meat infusions for routine growth at 37°C. These media contain peptides that are less toxic than free amino acids and typically can initiate logarithmic growth from smaller inocula than do synthetic media. The chemically defined medium of Higuchi et al. (1959) and its derivatives (Price et al., 1991; Zahorchak et al., 1979) have provided useful information about specific nutritional requirements at 37°C relating to virulence. Paramount among these is a need for Ca^{2+} (<2.5 mM) at host temperature but not at 26°C (Kupferberg and Higuchi, 1958). The necessity for Ca^{2+} at 37°C is enhanced by -20 mM Mg^{2+} (Brubaker and Surgalla, 1964; Higuchi et al., 1959; Higuchi and Smith, 1961) but largely can be eliminated by removing Na^+ from the medium (Fowler and Brubaker, 1994) and, at least at elevated pH, by adding nucleoside

diphosphates and triphosphates (Zahorchak and Brubaker, 1982). The basis of this unusual nutritional requirement is discussed under Physiology and its consequences in mediating pCD-encoded virulence effectors within the mammalian host are considered under Disease. Organisms starved of Ca^{2+} at 37°C in vitro undergo bacteriostasis, upregulation of pCD-encoded effectors of virulence (i.e., cytotoxic Yops and LcrV), and concomitant reduction in adenylate energy charge (Zahorchak et al., 1979). As a consequence, the bacterial population shifts (Fukui et al., 1957) to reflect selection of avirulent Ca^{2+} -independent mutants lacking pCD. A comparison of the kinetics of bacteriostasis in chemically defined medium between *Y. pestis* and the enteropathogenic yersiniae is provided in Fig. 1.

It is generally recognized that the doubling times of *Y. pestis* are significantly greater than those observed for typical enteropathogenic yersiniae in media supplemented with Ca^{2+} . This difference largely disappears, however, if the concentration of atmospheric CO_2 is brought to 10% whereupon single cells of *Y. pestis* can form visible colonies at 37°C on enriched solid medium in 24 hours rather than the usual 2 days. The concentration of metabolic CO_2 generated in suitably enriched liquid media is sufficient to permit cells of *Y. pestis* to achieve doubling times during the mid-logarithmic growth phase of about 70 min at both 26° and 37°C. As shown in Fig. 1, this value approximates that observed for enteropathogenic yersiniae cultivated in the

same medium (Carter et al., 1980). Despite the marked differences in physiology between yersiniae grown at 26°C versus 37°C, the organisms respond rather slowly to shifts in temperature and changes in availability of nutrients. For example, a lag phase of many hours occurs upon use of bacteria previously cultivated at 5°C as inocula for liquid media incubated at higher temperatures, especially 37°C. The basis for this inefficient regulation is not fully resolved but may reflect deficiencies in global control processes or reliance upon regulatory mechanisms involving quorum sensing. To assure steady state kinetics in liquid cultures, it is therefore imperative to utilize late-logarithmic, growth-phase cells by subculturing them two or three times in the same medium before performing experiments. Claims in the old literature that cells of *Y. pestis* grow more rapidly at room temperature than at host temperature are incorrect and probably reflect ignorance of sluggish regulation, the nutritional requirement for Ca^{2+} , and the stimulatory effect of CO_2 .

Physiology

Intermediary Metabolism

Results of early studies indicated that plague bacilli possess complete Embden-Meyerhoff (glycolytic), hexose-monophosphate (pentose phosphate), and tricarboxylic acid (Krebs cycle)

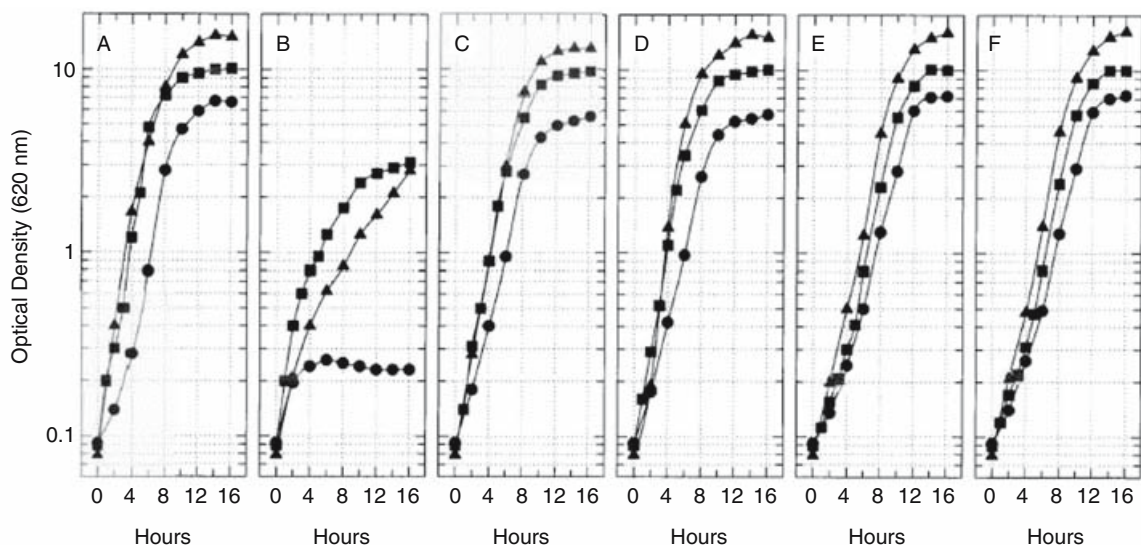

Fig. 1. Growth of *Y. pestis* KIM10 (●), *Y. pseudotuberculosis* PB1 (■), and *Y. enterocolitica* WA (▲) in chemically defined medium (Zahorchak and Brubaker, 1982); incubation of pCD/pYV⁺ cells at 37°C plus (A) 2.5 mM Ca^{2+} or without (B) added Ca^{2+} , pCD/pYV⁻ cells at 37°C plus (C) 2.5 mM Ca^{2+} or without (D) added Ca^{2+} , and pCD/pYV⁺ cells at 26°C plus (E) 2.5 mM Ca^{2+} or without (F) added Ca^{2+} . Significant concentrations of pCD/pYV-encoded virulence effectors and the attendant translocation apparatus are only expressed in vitro during restriction of vegetative growth at 37°C in the Ca^{2+} -deficient medium (B). Data from Carter et al. (1980).

pathways. As noted in later reviews (Brubaker, 1991; Brubaker, 1972; Perry and Fetherston, 1997), all three of these suppositions may be incorrect. For example, attempts to detect glucose 6-phosphate dehydrogenase in *Y. pestis* were not successful under conditions that yielded positive results for *Y. pseudotuberculosis* (Mortlock, 1962a; Mortlock and Brubaker, 1962b). This enzyme is central to the hexose-monophosphate pathway, and its absence necessitates *in vitro* synthesis of pentose from hexose by reversal of the normal physiological reactions catalyzed by transketolase and transaldolase. The deficiency does not, of course, prohibit synthesis of pentose from D-gluconate, which, incidentally, upregulates a functional Entner-Doudoroff pathway (Mortlock, 1962a). Analogous deficiencies of enzymes required for operation of the Embden-Meyerhoff pathway or tricarboxylic acid cycle have not been reported, but ancillary defects may very well modify the traditional roles of these catabolic systems. For example, cells of *Y. pestis* normally utilize the glyoxylate bypass as judged by expression of constitutive isocitrate lyase activity (Hillier and Charnetzky, 1981; Quan et al., 1982). The rationale for this modification of the tricarboxylic acid cycle is unknown. One possibility is that, despite early claims to the contrary, the organisms lack one or more enzymes of this pathway and therefore rely on the glyoxylate bypass to assure cycling of carbon (i.e., regeneration of oxalacetate). In favor of this notion is the observation of the very modest ability of extracts of *Y. pestis* to convert α -ketoglutarate to succinate (R. Brubaker, unpublished observations). Alternatively, because the glyoxylate bypass typically serves to generate tricarboxylic acid cycle intermediates such as malate from two-carbon fragments (i.e., acetate), it may function in *Y. pestis* to restore oxalacetate (lost upon transformation to L-aspartate). Levels of pyruvate kinase, an enzyme of the Embden-Meyerhoff pathway, also were modest in *Y. pestis* as opposed to *Y. pseudotuberculosis* (R. Brubaker, unpublished observations). Again, as noted below, this result may reflect adjustment of intermediary metabolism to accommodate loss of the oxalacetate pool during growth *in vitro*.

An appreciation of the central role of aspartase in bacterial catabolism is essential in understanding the critical consequences of its mutational loss in *Y. pestis*. This enzyme catalyzes the conversion of L-aspartate to the tricarboxylic cycle intermediate fumarate, which is then converted to malate before undergoing dehydrogenation in a reaction yielding NADH and oxalacetate. The latter fulfills a central role in intermediary metabolism by serving as a substrate in reactions essential to catabolism (formation of citrate for use in the

tricarboxylic acid cycle) and anabolism (formation of the aspartate and pyruvate families of amino acids). It is now recognized that equilibria favoring accumulation of oxalacetate generally stimulate growth of plague bacilli *in vitro*, whereas equilibria facilitating oxaloacetate destruction are detrimental. For example, Baugh et al. (1964) found oxalacetate to be the primary product of CO_2 fixation, thereby providing an explanation for the ability of this gas to stimulate growth. On the other hand, L-glutamate hastened restriction of plague bacilli cultivated in Ca^{2+} -deficient medium (Fowler and Brubaker, 1994) because the organisms can transaminate the oxalacetate pool to L-aspartate, which is then excreted into the supernatant fluid (Dreyfus and Brubaker, 1978). L-proline caused similar excretion in cells of *Y. pestis* but accumulation of L-aspartate did not occur in cultures of *Y. pseudotuberculosis* because the amino acid is promptly recycled into the tricarboxylic cycle as fumarate via the action of aspartase (Fig. 2). In view of these observations, it may be significant that reduced pyruvate kinase activity in *Y. pestis* grown with D-gluconate would promote accumulation of pyruvate, a substrate for the pyruvate carboxylase-mediated fixation of CO_2 into oxalacetate. As already noted, constitutive expression of the glyoxylate bypass would similarly favor restoration of the oxalacetate pool from two-carbon fragments.

Loss of metabolic carbon in the form of excreted L-aspartate accounts at least in part for the smaller number of plague bacilli found during stationary phase after growth under permissive conditions than terminal populations typically achieved by the enteropathogenic *Yersinia* (Fig. 1). Excretion of L-aspartate also contributes to the abrupt restriction of growth observed for cells of *Y. pestis* harboring pCD following shift to 37°C in Ca^{2+} -deficient medium. This prompt shutoff differed significantly from that observed for enteropathogenic *Yersinia* carrying pYV, which continued to multiply but at a slower rate (Fig. 1). However, a pattern of restriction essentially identical to that shown for the enteropathogenic *Yersinia* was obtained for *Y. pestis* by removing either L-glutamate or Na^+ from the medium (Fowler and Brubaker, 1994). The role of Na^+ in this context is not fully resolved but it is probably significant that this cation functions as an obligatory antiporter for transport of L-glutamate (Fujimura et al., 1983; MacDonald et al., 1977). In summary, loss of metabolic carbon in the form of L-aspartic acid seriously handicaps plague bacilli during cultivation *in vitro*, especially at 37°C in the absence of Ca^{2+} . This catabolic lesion resulting from species-specific mutational loss of aspartase need not, of course, cause loss of fitness *in vivo*. That is, host

Fig. 2. Degradation of L-glutamic acid (A) by resting cells of *Y. pseudotuberculosis* PB1 (▲) and *Y. pestis* EV76 (●) with accumulation of L-aspartic acid (■) by the latter; degradation of L-proline (B) by resting cells of *Y. pseudotuberculosis* PB1 (▼) and *Y. pestis* EV76 (●) with accumulation of L-aspartic acid (■) and L-glutamate (▲) by the latter. The reaction mixture contained -5 mg yersiniae, 33 μ moles Tris \cdot HCl (pH 8.5), 1.0 μ mole Mg^{2+} , and 10 μ moles of radioactive amino acid (0.1 μ Ci/ μ mole) in a volume of 1.0 ml; data from Dreyfus and Brubaker (1978).

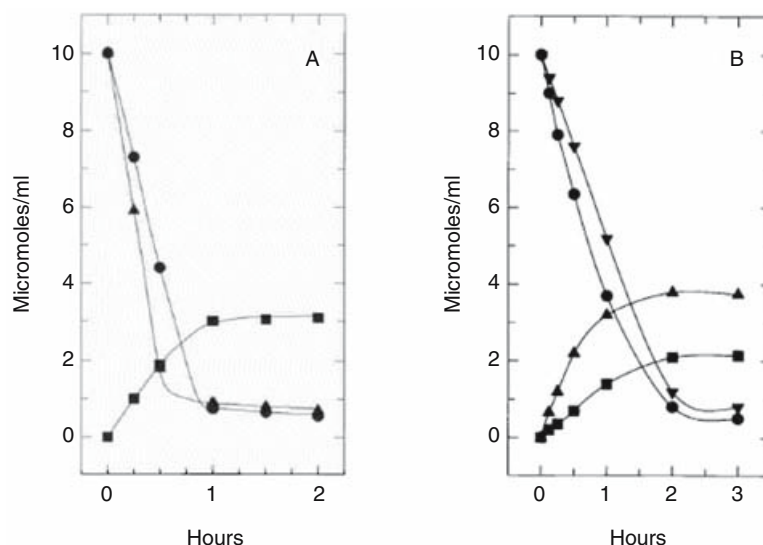

Table 2. Initial rates of destruction of some catabolizable amino acids by resting cells of *Y. pestis* EV76 and *Y. pseudotuberculosis* PB1 in 0.033 M MOPS buffer, pH 7.0^a .

Amino acid	Rate of destruction (nmol of amino acid/min/mg dry weight)		Ratio
	<i>Y. pestis</i>	<i>Y. pseudotuberculosis</i>	
L-Aspartate	0	31.0	>31
L-Asparagine	6.4	46.6	7.3
L-Glutamate	2.5	10.2	4.1
L-Glutamine	0	2.2	>2.2
L-Serine	243.8	53.1	0.2
Glycine	18.1	5.8	0.3
L-Alanine	12.8	9.3	0.7
L-Proline	11.9	11.3	0.9
L-Threonine	7.7	10.1	1.3

Abbreviations: MOPS, 3-(N-morpholino) propane sulfonate.

^aData from Dreyfus and Brubaker (1978).

enzymes would be expected to regenerate L-glutamate from the excreted L-aspartate at the expense of significant metabolic energy. Further study of this phenomenon is required to determine whether it contributes to expression of acute disease.

A comparison of the ability of *Y. pestis* and *Y. pseudotuberculosis* to catabolize the naturally occurring dicarboxylic amino acids, their amines, and some additional catabolizable amino acids is shown in Table 2. The increased rates of destruction determined for L-glutamate, L-glutamine, L-aspartate and L-asparagine in *Y. pseudotuberculosis* undoubtedly reflects the absence of aspartase in *Y. pestis*. However, the remaining catabolizable amino acids were degraded at similar rates with the exception of L-serine, which was destroyed at an exorbitant pace by plague bacilli (Dreyfus and Brubaker, 1978). This phenomenon results as a con-

sequence of constitutive serine deaminase activity (R. Brubaker, unpublished observations). Unregulated destruction of L-serine may have some bearing on the observation that cells of *Y. pestis* require glycine, which can be obtained from L-threonine, probably via threonine aldolase, but not from L-serine, which is known to be the immediate precursor of glycine in *E. coli* (Brubaker and Sulen, 1971). This observation suggests mutational loss of serine hydroxymethyltransferase or an as yet unsuspected defect at the level of folic acid metabolism. The nature of this and other unresolved peculiarities in the intermediary metabolism of *Y. pestis* will shortly become resolved upon publication of the completed sequence of its genome.

Global Regulation

Existence in plague bacilli of a functional ferric uptake regulator (Fur) system and cAMP-binding protein sequence for regulation of iron assimilation has been reported (Staggs and Perry, 1992). Mechanisms of macromolecular synthesis in *Y. pestis* have received intensive study. As might be anticipated, no significant modifications or innovations have been reported to exist in these typically conserved processes. Similarly, regulation of macromolecular synthesis evidently remains intact, in that plague bacilli are stringent (Charnetzky and Brubaker, 1982) and capable of ordered shutdown of protein, RNA and DNA synthesis during the onset of bacteriostasis prompted by Ca^{2+} -starvation at $37^\circ C$ or by normal entrance into stationary phase (Zahorchak et al., 1979). Nevertheless, global regulation at the level of small molecule metabolism may be defective as judged by the peculiarities in catabolism noted immediately above. In

this context, loss of leucine regulatory protein (Calvo and Matthews, 1994; Newman and Lin, 1995) would account for the uncontrolled destruction of L-serine and for many of the nutritional characteristics and sluggish regulation observed for *Y. pestis*. Inspection of the completely sequenced genome should provide an immediate resolution to these issues. Of special importance in this context was the discovery of genes mediating quorum sensing, including *lux*, in the partially sequenced genome (*Yersinia pestis* Sequencing Group, on-line).

The ability of plague bacilli to provide appropriate responses to temperature has received widespread attention. Major cold-shock proteins (MCSPs) mediate psychrotolerance in many diverse groups of bacteria including yersiniae. The three yersiniae pathogenic to humans (plus *Y. ruckeri*) possess two such cold-inducible chromosomally encoded tandem gene duplications that are able to transcribe both bicistronic (*cspA1/A2*) and monocistronic (*cspA1*) mRNA (Neuhaus et al., 1999). Transcription at 30°C was negligible, but temperature shift to 10°C or lower caused a prompt (at least 300-fold) increase in the bicistronic message and a more modest increase of the monocistronic form. Expression of cold-shock proteins (CspA1 and CspA2) was evident after 10 min, illustrating remarkable promptness of the system that upregulates them.

Less is known about the processes that enable yersiniae to adapt to host temperature. At least two mechanisms account for upregulation of virulence effectors following shift from 26 to 37°C. The first is regulated by LcrF (VirF in *Y. enterocolitica*), a pCD-encoded activator required for transcription of a plethora of structural genes located on the same plasmid (Cornelis et al., 1989; Cornelis, 1993; Lambert de Rouvroit et al., 1992). Temperature-dependent melting of DNA within specific internal domains of lcrF assures its transcription; these domains thus serve as the thermostat (Rohde et al., 1999). Once produced, this AraC-like transcriptional activator (Cornelis et al., 1989) binds to specific sequences upstream of other genes encoded by pCD, thereby assuring their expression (Wattiau and Cornelis, 1994). This process regulates the pCD-encoded type III secretion mechanism and attendant effectors of virulence. However, it does not regulate antigens 3, 4 and 5 (Crumpton and Davies, 1956) because these proteins retain normal thermoregulation following mutational loss of pCD. Antigens 3, 4 and 5 correspond to pMT-encoded Caf1, chromosome-encoded pH 6 antigen, and chromosome-encoded KatY, respectively; their structure and function is described below. Garcia et al. (1999a) found three DNA sequences upstream from *katY* that possessed significant homology with the consensus sequence for LcrF

(Wattiau and Cornelis, 1994). This finding is consistent with the prospect that there is an additional chromosomally encoded LcrF-like transcriptional activator. Furthermore, following shift from 26 to 37°C, thermoregulated mRNA of LcrF-activated functions encoded by pCD took significantly longer to appear than did thermoregulated mRNA of chromosomal genes such as *katY* (Garcia et al., 1999b). Preliminary evidence suggests that the pCD-mediated onset of bacteriostasis at 37°C in Ca²⁺-deficient medium can be hastened by undertaking the temperature shift in spent medium (R. Brubaker, unpublished observations). This phenomenon is consistent with quorum sensing and may provide an explanation for the existence of *lux* in the partially sequenced genome (*Yersinia pestis* Sequencing Group, on-line). To appreciate the role played by Ca²⁺ in downregulating LcrF-activated functions while facilitating growth at 37°C, the physiology of protein translocation mediated by the pCD-encoded type III secretion system (described below) must be understood.

Unique Functions Unrelated to Virulence

The majority of unusual or unique functions produced by plague bacilli are virulence factors that neutralize nonspecific mechanisms of host defense. Nevertheless, the organisms possess a limited number of singular mechanisms that facilitate survival in the flea (the abilities to absorb hemin or Congo red and elaborate murine toxin) and assure retention of pPCP (expression of the bacteriocin pesticin). The physiology of these attributes is considered below.

The *hms* LOCUS. Wild-type cells of *Y. pestis* possess the ability to absorb certain exogenous flat planar molecules including hemin (Jackson and Burrows, 1956b) and Congo red (Surgalla and Beesley, 1969) at temperatures of 26°C or less, which form pigmented or Pgm⁺ colonies on solid medium. Comparison of iron reservoirs in Pgm⁺ versus Pgm⁻ yersiniae revealed that only the former accumulated significant levels of hemin at the outer membrane and that this deposition failed to occur at 37°C (Perry et al., 1993). This capability is mediated by genes comprising the hemin storage or *hms* locus (Perry et al., 1990) located adjacent to the high-pathogenicity island encoding the ability to synthesize yersiniabactin (Bearden et al., 1997; Buchrieser et al., 1998b; Gehring et al., 1998; Heesemann, 1987). Use of the designation Hms⁺ indicates the ability to form pigmented colonies known to require an intact *hms* locus and functional *hmsT* gene defined below. These Hms⁺ isolates need not, of course, possess the linked high-pathogenicity island encoding yersiniabactin synthesis (or vice

versa). The *hms* locus comprises an *hmsHFRS* operon (Perry and Fetherston, 1997), although absorption of pigments also requires *hmsT* located outside of the deletable region (Jones et al., 1999). Expression of the *Hms*⁺ trait depends upon formation of a surface complex requiring expression of multiple gene products. The *HmsH* and *HmsR* proteins, evident on outer membranes, may mediate the stacking of planar molecules, which accounts for the color and brittle morphology of colonies grown at 26°C with exogenous hemin or Congo red. This phenotype is regulated by *Fur* despite the absence of salient binding sites near *hmsHFRS*; an appropriate potential *Fur*-binding site was later mapped near *hmsT* (Jones et al., 1999).

As noted under Disease, the high-pathogenicity island within the deletable *pgm* locus is essential for expression of plague; whereas, the *hms* locus is not (Lillard et al., 1999). However, Kuttyrev et al., (1992) discovered that *Pgmy* mutants were unable to effectively colonize the flea vector and this defect was shown by Hinnebusch et al. (1996) to reflect loss of the *hms* locus, rather than the high-pathogenicity island. The precise roles of *HmsH* and *HmsR* in facilitating blockade of the flea proventriculus are not resolved, but the phenomenon clearly involves physical adherence of the bacteria to the surface of the flea gut and to each other. This penchant of *Pgm*⁺ yersiniae to specifically undergo autoagglutination during growth at room temperature is observed in the absence of exogenous pigments and may account for the phenomenon of “stalactite” growth described in the early literature. Small planar molecules other than hemin and Congo red are readily absorbed as evidenced by the accumulation of radioactive guanine on the surface of *Pgm*⁺ but not *Pgmy* organisms. Indeed, the affinity of this purine for the bacterial surface was sufficiently strong to prevent its assimilation into cytoplasm and subsequent conversion to adenine (Brubaker, 1970b). The findings that *Pgm*⁺ yersiniae remain associated during growth as particulate masses and are unable to transport certain planar molecules suggest that expression of the *Hms*⁺ trait outside of the flea may be deleterious. If correct, this notion would explain the finding that almost all strains of *Y. pseudotuberculosis* are *Hms*⁺, although many possess an intact *hmsHFRS* operon (Buchrieser et al., 1998a; Hare et al., 1999b). The reason why the *Hms*⁺ trait is cryptic in *Y. pseudotuberculosis* is not fully resolved; an obvious possibility is downregulation at the level of *hmsT* (Hare et al., 1999b; Jones et al., 1999).

Murine Toxin

The *hms* locus serves to “block” the flea proventriculus with aggregated bacteria, which causes

regurgitation and repeated attempts at feeding. Though this phenomenon clearly enhances the possibility of infection, it is also eventually lethal to the vector (Perry and Fetherston, 1997). Murine toxin encoded on *pMT* is another determinant required for survival within the otherwise hostile environment of the flea midgut (Protsenko et al., 1983; Protsenko et al., 1991). Work by J. Hinnebusch and colleagues (Hinnebusch et al., 1998b; Hinnebusch et al., 1999) indicates that this toxic protein is required for colonization (as opposed to blockage) of the flea midgut. Many workers have assumed that the physiological role of murine toxin is to assure prompt death of murine hosts, thereby guaranteeing departure of the infected flea vector. This capability is considered below in more detail. The discovery that murine toxin is also necessary for survival in the flea was therefore unanticipated by some and provides another example illustrating dual functionality in virulence effectors of *Y. pestis*.

Pesticin

Ben-Gurion and Hertman (1958) discovered that wild-type strains of *Y. pestis* express a unique bacteriocin active against *Y. pseudotuberculosis* that they termed “pesticin.” Further study showed this inhibition was limited to serotype IA and IB cells of *Y. pseudotuberculosis*, highly invasive serovar O:8 isolates of *Y. enterocolitica*, and certain clinical strains of *E. coli* (including the universal colicin indicator strain θ (Brubaker and Surgalla, 1961). It is established that group B colicins utilize siderophore receptors to obtain entrance to sensitive bacteria and their antibacterial activity can be inhibited by exogenous Fe³⁺ that downregulates these receptors (Davis and Reeves, 1975). Pesticin was the first bacteriocin shown to exhibit this effect (Brubaker and Surgalla, 1961; Brubaker and Surgalla, 1962) and pesticin-insensitive mutants of *E. coli* θ displayed interesting patterns of tolerance but not resistance to group B colicins (Ferber et al., 1979b). However, attempts to characterize a siderophore capable of sharing the pesticin receptor (*Psn*) were unsuccessful until Heesemann (1987) discovered the elusive yersiniabactin (discussed under Phylogeny and Disease). Studies of the mode of action of pesticin revealed that the bacteriocin generated giant osmotically stable spheroplasts from sensitive bacteria (Hall and Brubaker, 1978). This capability, shown in Fig. 3, is unique among bacteriocins and can be utilized as a determinative assay for *Y. pestis*. Pesticin was purified to homogeneity and shown to exist as a monomeric peptide in two conformer states (Hu and Brubaker, 1974; Hu et al., 1972). The bacteriocin is not an *N*-acetylglucosaminidase as initially reported (Ferber and Brubaker, 1979a);

Fig. 3. Morphology of cells of *Y. enterocolitica* after cultivation for 6 h in the absence (A) and presence (B) of homogenous pesticin (40 U per ml); data from Hall and Brubaker (1978).

use of improved methods showed that muramidase activity accounts for peptidoglycan cleavage (Vollmer et al., 1997). Pesticin was initially sequenced by Motin and Brubaker (#U31974) and found to exhibit a molecular mass of 39.9 kDa; a BLAST search failed to yield close homologs. This lack of similarity is in accord with the finding of Vollmer et al. (1997) that the bacteriocin is entirely unique. *Yersinia* capable of producing pesticin are protected by a pPCP-encoded periplasmic immunity protein (Pils et al., 1996).

EFFECTORS OF VIRULENCE As noted under Disease, the virulence factors of *Y. pestis* are concerned with either facilitating bulk vegetative growth in favored visceral niches such as liver and spleen or dissemination of the bacteria to these organs from peripheral sites of infection initiated by fleabite. The chromosome and all three plasmids of the species encode virulence effectors. Their structure and function is described below.

pCD-Encoded Functions

Most shared virulence factors encoded by pCD/pYV promote cytotoxicity or prevent host reprisal by inhibiting inflammatory reactions required for activation of professional phagocytes. These functions provide the basis for the common symptoms of plague and the localized chronic afflictions caused by the enteropathogenic *yersiniae*. Paramount among these common determinants of virulence is the *yersiniae* outer proteins (Yops), which undergo direct introduction from the cytoplasm of the invading organism into the cytosol of host cells via the pCD/pYV-encoded type III secretion machine. This process of translocation is by injection and depends on docking of the bacterium to the target host cell, thereby minimizing intervention by the immune system. Those Yops that serve as effectors of virulence are often cytotoxic, as judged by their homology with known exotoxins of other species or with established modes of

catalysis. They lack the typical leader sequences of generic outer-membrane proteins, and specific chaperones are required to mobilize their type III secretion (Cornelis, 1998a; Cornelis, 1994; Cornelis et al., 1998b; Cornelis and Wolf-Watz, 1997). However, convincing evidence also has accumulated indicating that at least YopE is recognized and then translocated on the basis of unique non-coding mRNA configuration, rather than primary amino acid structure (Cheng et al., 1997; Lee and Schneewind, 1999). The major Yops were discovered independently in *Y. pseudotuberculosis* by Straley and Brubaker (1981) and in *Y. enterocolitica* by Portnoy et al. (1981b). In wild-type isolates of *Y. pestis*, net synthesis of Yops is not detected in vitro (Chalvignac et al., 1988; Kuttyrev et al., 1999; Mehig and Brubaker, 1993; Mehig et al., 1989; Sample and Brubaker, 1987a; Sample et al., 1987b; Straley and Brubaker, 1981). This difference provides a major distinction between plague bacilli and the enteropathogenic *yersiniae* and is discussed below and under Disease. At least six Yops directly or indirectly promote tissue damage.

The first of these virulence determinants, YopE, causes rounding of nonprofessional phagocytes (e.g., HeLa cells) by disrupting actin microfilaments, exhibits antiphagocytic activity, and is essential for full virulence (Rosqvist et al., 1990; Rosqvist et al., 1991; Straley and Bowmer, 1986; Straley and Cibull, 1989; Straley et al., 1993). In a seemingly unrelated phenomenon, YopE selectively facilitates invasion-dependent cytotoxicity of lymphoblasts by *Y. pseudotuberculosis* in an RT1-A-restricted, CD8⁺ T cell-mediated reaction (Falgarone et al., 1999). A second cytotoxin (YopT) can similarly disrupt the host cell cytoskeleton; unlike YopE, YopT is not essential for lethality (Iriarte and Cornelis, 1998a). An essential virulence factor (YopH; Bölin and Wolf-Watz, 1988; Straley and Bowmer, 1986) has protein-tyrosine phosphatase activity (Bliska et al., 1991; Guan and Dixon, 1990). This effector is also cytotoxic and was reported to prevent assembly of macrophage focal adhesions

required for phagocytosis (Persson et al., 1997) and to block early Ca^{2+} -signalling in neutrophils (Andersson et al., 1999). The YopJ determinant (YopP in *Y. enterocolitica*) is essential for full virulence of *Y. pseudotuberculosis* in mice, where it binds directly to salient members of the mitogen-activated protein kinase superfamily (Orth et al., 1999), thereby downregulating TNF- α with concomitant apoptosis of macrophages (Monack et al., 1998; Monack et al., 1997; Palmer et al., 1998; Palmer et al., 1999). This capability was suggested (Mills et al., 1997; Monack et al., 1998; Palmer et al., 1998; Schesser et al., 1998) to account, at least in part, for the remarkable ability of yersiniae to downregulate expression of the major proinflammatory cytokines IFN- γ and TNF- α (Nakajima and Brubaker, 1993). Nevertheless, YopJ is not essential for lethality of *Y. pestis*, at least in the murine system (Straley and Bowmer, 1986). This discrepancy probably reflects the fact that plague is lethal in mice before significant intervention by macrophages can occur. Further study likely will demonstrate that YopJ also is essential for lethality in more resistant rodents indigenous to natural sylvatic reservoirs, as well as in humans. Mutants lacking YopM also retain significant virulence in mice; the physiological role of this virulence effector and the consequences of its loss in other hosts are unknown (Boland et al., 1996; Nemeth and Straley, 1997). The YpkA determinant (or YopO in *Y. enterocolitica*) is necessary for lethality in the murine model; this protein possesses serine/threonine kinase activity (Galyov et al., 1993). The YopB and YopD determinants are established components of the type III secretion machine, but they also possess independent abilities to form pores in membranes and may thus contribute to host cell necrosis. This effect is dramatic in the case of YopB, which has hemolytic activity (Håkansson et al., 1996).

Since its discovery by T. W. Burrows in 1956 (Burrows, 1956), LcrV (V antigen) has remained in the forefront of yersiniae research. This 37.3-kDa (327-amino acid residue) pure protein (Motin et al., 1992) is unstable and undergoes marked degradation during purification by traditional chromatographic procedures (Brubaker et al., 1987; Motin et al., 1994). Nevertheless, LcrV expressed in *E. coli* in the form of fusion proteins engineered to contain the ligands staphylococcal Protein A (Motin et al., 1994; Nakajima et al., 1995), glutathione S-transferase (Leary et al., 1995), or sequences encoding polyhistidine (Anderson et al., 1996; Motin et al., 1996; Schmidt et al., 1999) can readily be purified to homogeneity by ligand affinity chromatography. Nevertheless, considerable care must still be taken during affinity chromatography to avoid denaturation causing loss of anti-inflammatory

activity and inability to interact with other pCD-encoded proteins; ability to raise protective antibodies is less dependent on maintenance of secondary structure (Motin et al., 1996; Nedi-alkov et al., 1997). For example, Motin et al. (1996) employed buffers of sufficient ionic strength to avoid nonspecific binding between polyhistidine-linked LcrV and LcrH; failure to avoid this pitfall may have prompted the report that this interaction was an "artifact" (Fields et al., 1997). The ability of LcrV fusion proteins to immunize against plague and to downregulate proinflammatory cytokines is discussed under Disease and Applications. Two additional roles of LcrV are considered below, which involve regulating construction of the pCD-encoded type III secretion machine and targeting the translocation of cytotoxic Yops from docked yersiniae into host cell cytoplasm.

pMT-Encoded Functions

Structural genes encoding capsular Caf1 antigen (*cafI*) and murine toxin (*ymt*) are encoded by pMT (Protsenko et al., 1983; Protsenko et al., 1991). The former resides within an evident high-pathogenicity island as judged by sequencing the entire plasmid (Hu et al., 1998; Lindler et al., 1998). The primary structure of Caf1 deduced by this process was identical to that first determined upon cloning (Cherepanov et al., 1991; Galyov et al., 1990). Although initially described as a glycoprotein, Caf1 is now recognized as a 15.5-kDa pure protein capable of undergoing polymerization to form a bilayer presenting a hydrophilic exterior surface. These polymers can achieve sizes of many megadaltons (Vorontsov et al., 1990) and assure uniform suspension of the organisms during cultivation at 37°C. This determinant confers resistance to uptake by certain professional phagocytes, especially neutrophils and monocytes, but it evidently is ineffective against fixed macrophages lining the capillary network of liver and spleen. This limited ability to protect against phagocytosis in vivo explains, in part, why mutation to Caf1⁻ delays, but does not decrease, lethality in the mouse, although a 100-fold reduction in the guinea-pig 50% lethal dose (LD50) was observed (Burrows, 1963; Burrows and Bacon, 1958). Similarly, Caf1⁻ mutants provided by aerosol were fully virulent in African green monkeys (Davis et al., 1996), and Caf1-deficient but otherwise typical plague bacilli have been isolated at human autopsy (Winter et al., 1960). Functions other than protection against phagocytosis have been proposed including roles in adhesion. It is interesting in this context that the periplasmic Caf1 chaperone (Caf1M) belongs to a family also involved in assembly of simple surface adhesions as opposed

to FGS chaperones concerned with assembly of complex adhesins such as pili (Chapman et al., 1999). Furthermore, Caf1 was found to exhibit sequence homology and three-dimensional similarity with the interleukin-1 receptor antagonist IL-1ra. Nevertheless, the antigen did not express significant IL-1ra activity or otherwise downregulate proinflammatory cytokines (Krakauer and Heath, 1998).

Murine toxin has been viewed as a significant virulence effector since its discovery by Ramon et al. (1947). As judged by the sequence of its cloned structural gene, native murine toxin probably exists as a 244-kDa tetramer of a 61-kDa primary translational product (Cherepanov et al., 1991). This protein is not toxic in many hosts including guinea pigs and tested primates. However, purified preparations of differing subunit composition have yielded LD50's of 0.2 to 3.7 μ g in laboratory mice (Perry and Fetherston, 1997). As a consequence, this protein probably is instrumental in causing the prompt death of *Muridae* (Old World rats and mice) during epidemics, thereby assuring the dispersal of infected fleas. Intensive early work on the ability of murine toxin to selectively kill *Muridae* has been reviewed (Brubaker, 1972; Perry and Fetherston, 1997). Resolution of the correct mode of action, however, awaited the results of a BLAST search demonstrating significant homology with phospholipase D (Perry and Fetherston, 1997); murine toxin is now established as a prototype member of the phospholipase D superfamily (Rudolph et al., 1999). A second, and possibly primary, role of murine toxin in facilitating survival in the flea is discussed above.

pPCP-Encoded Functions

Of the three structural genes present in pPCP, only *pla* encodes an effector of virulence (Sodeinde and Goguen, 1988a); elimination of this function, like loss of *ymt* or *lcrV*, has profound pleiotropic consequences. A particulate fibrinolysin (Pla) discovered by Madison (1936) was later found to activate plasminogen (Beesley et al., 1967). Fractionation of yersiniae resulted in recognition of two forms of the protein in the outer membrane termed α - and β -Pla (Straley and Brubaker, 1982). Specific message is translated as a transient 34.6-kDa protein that is processed upon insertion into the outer membrane to yield 32.6-kDa α -Pla. The latter is then converted, probably by shearing, in \sim 2 hours to slightly smaller β -Pla (Mehigh et al., 1989; Sodeinde and Goguen, 1988a). Both forms bound tenaciously to the outer membrane of *Y. pestis*. However, cells of *E. coli* transformed with pPCP produced only α -Pla that could be readily extracted in soluble form with 1 M NaCl as a

mixture of α -Pla, sheared α -Pla, and smaller forms (Kutyrev et al., 1999). The reason for this discrepancy between yersiniae and *E. coli* is not fully understood, but Pla possesses significant homology with OmpT from the latter (Sodeinde and Goguen, 1989) and may therefore undergo faulty anchoring to the outer membrane of some isolates of this species. Invasion of tissues is accomplished by Pla-dependent adherence to host basement membrane and extracellular matrix, where plasminogen activation facilitates bacterial metastasis (Lähteenmäki et al., 1998). Isolates (pPCP⁺) of *Y. pestis* also can activate prothrombin and thereby coagulate mammalian plasma (Beesley et al., 1967; Eisler, 1961). This function also is accomplished by Pla (Sodeinde and Goguen, 1988a; Sodeinde et al., 1988b). Despite the suggestion that coagulase activity is of limited importance (Sodeinde et al., 1992), the capability may have serious consequences during terminal disease (Eisler, 1961; Finegold et al., 1968).

Expression of Pla is associated with the marked ability of *Y. pestis* to colonize the viscera and thus cause lethal infection upon administration by peripheral (i.e., intradermal, subcutaneous or intraperitoneal) routes of infection. The determinant is not required to initiate lethal disease by intravenous injection, which provides immediate access to fixed macrophages lining the capillary beds of liver and spleen (Brubaker et al., 1965). This relationship, illustrated in Table 3, was verified with isogenic *pla* mutants of epidemic *Y. pestis* strains KIM (Sodeinde et al., 1992) and CO92 (Welkos et al., 1997). Nevertheless, equivalent changes in virulence were not detected in Pla-deficient isolates of *Pestoides* isolates (Samoilova et al., 1996; Welkos et al., 1997); further studies will be required to determine if the latter possess an additional tissue invasin.

Chromosome-Encoded Functions

Early studies with *Y. pestis* were instrumental in defining the general importance to pathogenic bacteria of possessing mechanisms capable of high-energy assimilation of iron in vivo. High frequency deletion of the entire *pgm* locus significantly reduces virulence by the intraperitoneal (Jackson and Burrows, 1956a) but not intravenous route of injection (Une and Brubaker, 1984b). It was recognized at the outset that this mutation causes a lesion in ability of *Y. pestis* to assimilate iron because concomitant injection of sufficient Fe³⁺ to saturate serum transferrin phenotypically restored full virulence (Jackson and Burrows, 1956b). However, Pgm⁻ yersiniae grow well in marginally iron-deficient media, thus verification of a Pgm⁺-dependent lesion in iron transport requires introduction of improved

Table 3. Influence of phenotypic traits on 50% lethal doses of *Yersinia pestis* and *Yersinia pseudotuberculosis* by intravenous, intraperitoneal and subcutaneous routes of injection in control mice and in mice injected with sufficient iron to saturate serum transferrin.

Phenotype			Injected Fe ³⁺ (40 µg/mouse) ^a	Route of injection		
pCD	pPCP	Pgm		Intravenous	Intraperitoneal	Subcutaneous
				LD ₅₀		
<i>Yersinia pestis</i>						
+	+	+	n	8.1 × 10 ⁰	9.9 × 10 ⁰	6.1 × 10 ⁰
+	+	+	y	9.8 × 10 ⁰	9.8 × 10 ⁰	5.9 × 10 ⁰
–	+	+	n	>5 × 10 ⁷	>5 × 10 ⁷	>5 × 10 ⁷
–	+	+	y	>5 × 10 ⁷	>5 × 10 ⁷	>5 × 10 ⁷
+	0	+	n	7.1 × 10 ¹	3.8 × 10 ⁵	>5 × 10 ⁷
+	0	+	y	2.3 × 10 ¹	1.4 × 10 ¹	>5 × 10 ⁷
+	+	0	n	1.5 × 10 ¹	>5 × 10 ⁷	>5 × 10 ⁷
+	+	0	y	4.3 × 10 ¹	2.4 × 10 ¹	N.C. ^b
<i>Yersinia pseudotuberculosis</i>						
	pYV ⁺		n	3.9 × 10 ¹	2.9 × 10 ⁴	1.1 × 10 ⁴
	pYV ⁺		y	3.1 × 10 ¹	2.0 × 10 ²	1.4 × 10 ²
	pYV [–]		n	>5 × 10 ⁷	>5 × 10 ⁷	>5 × 10 ⁷
	pYV [–]		y	>5 × 10 ⁷	>5 × 10 ⁷	>5 × 10 ⁷

Symbols: pCD, pestis virulence plasmid; pPCP, pesticin-producing plasmid; Pgm, pigmentation phenotype; LD₅₀, 50% lethal dose; +, phenotype positive; – phenotype negative; 0, phenotype absent; y, injected; n, not injected; pYV, enterocolitica virulence plasmid.

^aIron was administered intraperitoneally as Fe²⁺.

Summary of data from: Brubaker (1965); Mehig et al. (1989); Une and Brubaker (1984).

methods to remove trace levels of the cation. Curiously, multiplication at 26°C was not inhibited in this environment. Attempts to resolve this issue have now established that plague bacilli utilize at least three chromosomally encoded high-affinity mechanisms to scavenge Fe³⁺ in vivo. These processes consist of the siderophore (yersiniabactin)-dependent process encoded by the high-pathogenicity island within the *pgm* locus (Bearden et al., 1997; Buchrieser et al., 1998b; Guilvout et al., 1993; Heesemann, 1987; Rakin et al., 1994), a siderophore-independent yersiniae ferric uptake (Yfu) system (Braun, 1997; Perry, personal communication, 1999), and a siderophore-independent ABC transporter (Yfe) system (Bearden et al., 1998). An additional ill-defined mechanism also may function during growth at 26°C but not 37°C (Lucier et al., 1996; Sikkema and Brubaker, 1987). Furthermore, distinct genes encode products enabling cells of *Y. pestis* to directly utilize hemin and hemoproteins as nutritional sources of iron (Hornung et al., 1996). Loss of this system for assimilating organic forms of iron does not reduce virulence, at least in the mouse (Thompson et al., 1999).

Discovery of two high-molecular-weight proteins termed HMWP1 and HMWP2 (Carniel et al., 1989; Guilvout et al., 1993) provided the basis for establishing the ribosome-independent mechanism of yersiniabactin synthesis. Yersiniabactin is a member of a new class of siderophores

that generally have a lower affinity for Fe³⁺ (yersiniabactin $K_D = 4 \times 10^{36}$) than environmental siderophores such as enterochelin ($K_D = 10^{52}$; Gehring et al., 1998); indeed, yersiniabactin was not detected by methods used to determine the stronger ligands (Perry and Brubaker, 1979). Biosynthesis is Fur-regulated (Staggs and Perry, 1992) and constitutes a process dependent upon eleven genes comprising regulatory (*ybtA*), synthetic (*irp2-ybtE*), and transport (*ybtP-ybtS*) operons (Gehring et al., 1998). The structural gene for the unprocessed form of the outer-membrane yersiniabactin receptor (*psn*) maps in this sequence, whereas *ybtP* and *ybtQ* encode inner-membrane permeases required for manipulation of the charged complex. Construction of yersiniabactin involves modular passage of covalent intermediates from the amino terminus of the *irp2* product (HMWP2) to the carboxyl terminus of the *irp1* product (HMWP1). The protein YbtX probably maintains tertiary structure as judged by its hydrophobicity and transmembrane domains. The proteins YbtS, YbtT and YbtE facilitate salicylate, thioesterase and salicyl-AMP metabolism, and YbtA is an AraC-like regulator that promotes transcriptional activation of *psn*, *irp2* and *ybtP*. S-Adenosylmethionine and malonyl-CoA provide the methyl moieties and linker between the thiazoline and thiazolidine rings, respectively. The role of YbtU is unknown but this protein is necessary for biosynthesis (Perry, personal communication, 1999). Pgm[–] mutants

(lacking the entire 102-kb locus) are mimicked with respect to avirulence by isolates possessing point mutations within salient genes comprising the yersiniabactin high-pathogenicity island (Bearden et al., 1997). This finding suggests that the ability to express and utilize yersiniabactin per se accounts for the Pgm⁺-dependent capability of *Y. pestis* to invade the viscera from peripheral sites of infection. Nevertheless, genes encoding putative virulence factors have been mapped between the *hms* locus and high-pathogenicity island that also may contribute to invasiveness (Buchrieser et al., 1999).

The reason why yersiniabactin is dispensable following infection via intravenous injection is not fully resolved. One likely possibility is that host-cell cytoplasm, potentially rich in ferritin-bound and other forms of organic iron, is promptly accessed following intravenous injection. It is therefore significant that mutational loss of the siderophore-independent Yfe or ABC transporter system by Pgm⁻ yersiniae (unable to synthesize yersiniabactin) resulted in absolute avirulence (LD₅₀ <10⁷ bacteria) by all routes of injection (Bearden and Perry, 1999). Virulence of mutants cured of pPCP, like those lacking the *pgm* locus, could be restored upon peripheral injection by administration of sufficient iron to saturate serum transferrin (Brubaker et al., 1965). This finding, shown in Table 3, was unexpected because loss of pPCP does not influence the ability of yersiniae to assimilate Fe³⁺. It is now recognized that injected (but not necessarily ingested) iron can inhibit a number of nonspecific mechanisms of host defense (van Asbeck and Verhoef, 1983) and that this situation probably accounted for the ability of iron to enhance the invasiveness of Pla⁻ mutants. Indeed, injected iron even restored the virulence of a mutant lacking otherwise essential pCD-encoded cytotoxic YopE (Mehigh et al., 1989).

Cells of *Y. pestis* express at least two additional chromosomally encoded factors that are associated with pathogenicity and shared with *Y. pseudotuberculosis* but not *Y. enterocolitica*. These determinants comprise two of the three temperature-dependent antigens of Crumpton and Davies (1956). The first such activity was designated antigen 3 and is equated with pMT-encoded Caf1. Remaining antigens 4 and 5 are now termed Psa (pH 6 antigen) and KatY, respectively. The reference to pH 6 refers to the penchant of this outer membrane adhesin to undergo optimal synthesis at slightly acidic pH (Bichowsky-Slomnicki and Ben-Efraim, 1963). Mutational loss of pH 6 antigen results in only modest reduction of virulence (Lindler et al., 1990); the minimum target determinant required for binding is β 1-linked galactosyl residues in glycosphingolipids (Payne et al., 1998). Some

Psa⁻ mutants, like those unable to express Caf1, tend to undergo autoagglutination after growth at 37°C (Crumpton and Davies, 1956). The specific activity of catalase-peroxidase in *Y. pestis* is among the highest reported in prokaryotes (Burrows et al., 1964). This value is due in part to production of a major protein now termed "KatY," which has marked homology with KatP, a virulence plasmid-encoded catalase-peroxidase of enterohemorrhagic *E. coli* O157:H7 (Garcia et al., 1999a). The consequences of mutational loss of KatY on virulence have not yet been determined but, in view of its abundant temperature-conditional synthesis, it seems possible that the enzyme facilitates expression of disease. One role for KatY is scavenging hydrogen peroxide (H₂O₂) generated by professional phagocytes, and thereby defeating oxygen-dependent processes of killing. If this mechanism can be verified, further work will be required to determine whether the high catalase activity of plague bacilli contributes to initial survival in fixed macrophages of liver and spleen or in free phagocytic cells encountered during the journey from dermis to viscera. The protein KatY also may function in vivo to degrade H₂O₂ or organic peroxides generated as terminal electron acceptors in oxygen-deficient niches. It is of interest that KatY, like Yops, is at least partially hydrolyzed by Pla suggesting a transient association with the outer membrane (Garcia et al., 1999b).

REGULATION OF VIRULENCE Shared pCD/pYV encodes an "anti-host genome" (Cornelis et al., 1998b) capable of mediating destruction of mammalian tissue while maintaining the deception that tissue necrosis is under control and the healing process may commence. The type III secretion machine encoded on this plasmid is the engine of virulence in all yersiniae pathogenic to mammals (Cornelis, 1998a; Cornelis et al., 1998b). The localization and description of open reading frames (ORFs) and noncoding elements of pCD1 of *Y. pestis* KIM are shown in Table 4. Many of these genes were initially thought to encode regulatory (*lcr*), type III secretion (*ysc*), virulence effector (*yop*), or chaperone (*syc*) functions. The original epithets have often been retained in cases where the product was later found to fulfill some distinct or bifunctional role. The ability of plague bacilli to undergo bacteriostasis in vitro in Ca²⁺-deficient media while expressing the pCD-mediated type III secretion system and attendant effectors of virulence is termed "the low-calcium response" or LCR (Goguen et al., 1984). Higuchi and Smith (1961) found that avirulent Ca²⁺-independent mutants are selected at 37°C at a rate of 10⁻⁴ on a medium containing magnesium oxalate; the majority of these mutants are now known to have lost pCD.

Table 4. Localization and description of open reading frames and noncoding elements in pCD1.

ORF or non-coding element	Position no.	Size		Description		
		Amino acids	Mass (kDa)	Orientation	Gene	Function

Data from Hu et al. (1998) and Perry et al. (1998).

However, point mutations on pCD of similar phenotype also can be selected with this medium. These mutants, like isolates cured of pCD, are not only Ca^{2+} -independent but also lack expression of the type III secretion mechanism and attendant virulence factors. This type of mutant was instrumental in defining the regulation and physiology of type III secretion. Paramount among Ca^{2+} -independent point mutations is *lcrF* noted above, which encodes a general transcriptional activator of pCD-encoded functions (Cornelis et al., 1989; Cornelis, 1993; Hoe and Goguen, 1993; Lambert de Rouvroit et al., 1992; Skurnik and Toivanen, 1992; Wattiau and Cornelis, 1994) and acts as the thermostat recognizing host temperature (Rohde et al., 1999).

Another example is *lcrV*, encoded within the *lcrGVH-yopBD* operon (Bergman et al., 1991; Perry et al., 1986; Price et al., 1989b). A multifunctional protein (LcrV; Skrzypek and Straley, 1995) was initially implicated as both a regulator of the LCR (Bergman et al., 1991; Price et al., 1991) and a virulence factor (see Disease in this

Chapter). However, evidence has not appeared as yet demonstrating a classical role for LcrV in DNA binding or other traditional forms of transcriptional control. The mechanism whereby LcrV upregulates other LcrF-activated gene products is not fully resolved but its export from the bacterium was found to depend upon interaction with genetically linked LcrG (Nilles et al., 1997). This observation is consistent with the prospect that LcrV removes excess LcrG by titration. It is, therefore, the latter that actually functions to downregulate LcrF-activated functions. The finding that LcrG serves to facilitate excretion of LcrV was extended by Sarker et al. (1998a), who reported that LcrG also is required for mobilization of cytotoxic Yops during their translocation. Excellent evidence has now accrued indicating that LcrV is an integral component of the type III secretion machine where it serves to facilitate translocation of effector Yops or extrusion of other components of the translocation apparatus (Fields et al., 1999b; Nilles et al., 1998; Pettersson et al., 1999; Sarker

et al., 1998b). Nevertheless, export of LcrV itself is not dependent upon the pCD-encoded secretion machine as demonstrated by its translocation by an independent chromosomally encoded type III secretion system (Fields and Straley, 1999a). Additional Ca^{2+} -independent variants exist including *lcrD* encoding an inner-membrane core-secretion function (Plano and Straley, 1981). So-called “ Ca^{2+} -blind” mutants constitute a second phenotype (Goguen et al., 1984) that has been equally instrumental in defining the LCR. These isolates are temperature-sensitive in that they are unable to sustain vegetative growth at 37°C even in the presence of sufficient Ca^{2+} to assure multiplication of the parent. In addition, Ca^{2+} is generally unable to downregulate LcrF-activated genes in these mutants, although thermoregulation of LcrF-activated gene products remains normal. As might be expected from the above, *lcrG* is a Ca^{2+} -blind mutant (Boyd et al., 1998; Skrzypek and Straley, 1993) by virtue of its inability to prevent accumulation of internal LcrF-activated gene products. This phenotype also is observed upon mutational loss of LcrE (YopN), which functions as a sensor of external Ca^{2+} (Forsberg et al., 1991). Other Ca^{2+} -blind mutants are *lcrR* (Barve and Straley, 1990) and both *yopD* (Håkansson et al., 1993) and its *lcrH* (*sysD*) chaperone (Bergman et al., 1991; Price and Straley, 1989a).

The YopD in concert with YopB and other pCD-encoded proteins noted below, initiate the type III secretion process used for translocation of cytotoxic Yops. The physiology of this process is illustrated in Fig. 4 from Fields et al. (1999b). The expression of virulence effectors translocated by the secretion machine is downregulated

by Ca^{2+} , which indirectly prevents their secretion, thereby promoting a form of negative feedback inhibition. Either removal of Ca^{2+} from the environment (especially in excess Mg^{2+}) or intimate contact with host cells in the presence of Ca^{2+} eliminates this block, whereupon LcrF-regulated determinants undergo prompt synthesis and export. Calcium may downregulate their exit in the absence of host cell contact by stabilizing an outer gate block of translocation channels mediated by LcrE (Forsberg et al., 1991) and TyeA (Iriarte et al., 1998b). Removal of the block by either withdrawal of Ca^{2+} or docking to host cells promotes dissipation of negative control upon secretion of the negative regulator LcrQ and YopD (Williams and Straley, 1998). The latter, in concert with YopB and LcrV, then forms a translocation pore modulated by YopK (Holmström et al., 1997). It is through this pore (raised from the basic secretion core foundation) that pCD-encoded cytotoxic Yops are translocated to targets located within host cell cytoplasm. Removal of the LcrG-mediated impediment by titration with internal LcrV clears the passage through which effector Yops enter the host cell (Nilles et al., 1998). The LcrV protein thus functions as both a structural component of the outer portion of the injection apparatus and as a cytoplasmic element required for retraction of LcrG from the inner gate of the secretion pore. As noted above, LcrV also is translocated to host cell cytoplasm via a separate process mediated by chromosomal genes (Fields and Straley, 1999a). As a consequence of this process, as well as its dissipation from the injection apparatus, considerable extracellular LcrV accumulates in vitro (Lawton et al., 1963) and in vivo (Smith et al., 1960).

Fig. 4. Model for the role of surface-located pCD-encoded proteins in mediating translocation of effector Yops. The Ysc creates a secretion channel through the bacterial inner membrane (IM), across the periplasm (PP), and through the outer membrane (OM). These pores remain blocked in the absence of direct contact with the eukaryotic cell plasma membrane (PM) by LcrE, TyeA and LcrG. The LcrV protein is associated with the extracellular surface of these closed pores directly or by association with another protein (X). Upon host cell contact, LcrE, TyeA and LcrG are displaced, and LcrV mediates formation of a delivery apparatus for transfer of Yops directly from the bacterium to the HeLa cell (eukaryotic) cytoplasm. (From Fields et al., 1999b).

The injection apparatus shown in Fig. 4 may exist in a dynamic state undergoing continuous reassembly (Fields et al., 1999b). Release of free YopB and YopD (like LcrV) during this process might therefore contribute to the overall lytic effect caused by delivery of the total package of cytotoxic Yops to host target cells. Tacit to these observations is the understanding that normal upregulation of at least one LcrF-activated gene product results in an as yet unknown bioenergetic drain that eventually promotes bacteriostasis in vitro. As noted above, this induction is normally prevented at room temperature by maintenance of inactive *lcrF* superstructure (Rohde et al., 1999) and at 37°C by Ca^{2+} -YopN interaction (Forsberg et al., 1991). Further study will be required to fully resolve the mechanism whereby Ca^{2+} prevents bacteriostasis at 37°C, but it is interesting that this cation is not required for full-scale growth upon removal of Na^+ and L-glutamate (Fowler and Brubaker, 1994). It is significant in this context that otherwise Ca^{2+} -blind *lcrE*, *lcrR*, and *lcrG* mutants, like the wild-type parent, express LcrF-activated genes and exhibit nearly full-scale growth in medium lacking both added Ca^{2+} and Na^+ (R. Brubaker, unpublished observations). However, neither *yopD* mutants nor isolates unable to express the YopD chaperone (*lcrH*) could multiply at 37°C in this environment. The temperature-sensitivity of the *yopD* mutant could, however, be fully suppressed by introduction of *lcrD*. These findings are consistent with the occurrence of two mechanisms of bacteriostasis. The first, as shown in Fig. 2, results from Na^+ toxicity to yersiniae expressing LcrF-mediated functions and may relate in part to loss of metabolic carbon. The second rests on the inability to produce or extrude YopD and may reflect the occurrence of physical damage caused by failure to construct a functional secretion machine.

This secretion process shown in Fig. 4 is distinct in the enteropathogenic yersiniae. Undelivered Yops produced by the latter, such as those expressed during cultivation in vitro at 37°C in Ca^{2+} -deficient media, are released into the supernatant fluid, become denatured, and nonspecifically absorb to the bacterial outer membrane as well as the culture vessels (Michiels et al., 1990). In contrast, undelivered Yops similarly produced by cells of *Y. pestis* harboring pPCP do not accumulate but rather undergo immediate posttranslational degradation (Fig. 5). The assumption that this phenomenon is mediated by Pla rather than pesticin or its immunity protein (Sample and Brubaker, 1987a; Sample et al., 1987b) was verified by genetic analysis (Sodeinde et al., 1988b). Transfer of pPCP to *Y. pseudotuberculosis* harboring pYV also prompted posttranslational degradation of Yops, although only partial

Fig. 5. Silver-stained gel (A) and corresponding autoradiogram (B) of trichloroacetic acid-precipitated material from cultures of *Y. pestis* KIM10 cultivated at 37°C in Ca^{2+} -deficient medium. Cells (pCD⁺, pPCP⁺) were pulsed for 15 s with ^{35}S -methionine and then chased with unlabeled methionine for 0 (lane 1), 15 s (lane 2), 30 s (lane 3), 1 min (lane 4), 2 min (lane 5), 4 min (lane 6), 8 min (lane 7), 15 min (lane 8), 30 min (lane 9) and 1 h (lane 10). Control lanes (pulsed for 15 s and then chased for 1 h) contained isogenic pCD⁺, pPCP⁺? (lane 11), pCD⁻, pPCP⁺ (lane 12), and pCD⁻, pPCP⁻ (lane 13) derivatives. Molecular weight markers in kDa are provided in the right margin and the positions of individual Yops are shown in the left margin; p24 indicates a stable YopE degradation product (Chalvignac et al., 1988). (From Kuttyrev et al., 1999.)

hydrolysis of the adhesin YadA was observed (Kuttyrev et al., 1999). As noted under Disease, undelivered Yops would be recognized as foreign protein and would thus promote inflammation. The ability of *Y. pestis* to eliminate this material from its immediate vicinity during growth in necrotic visceral lesions could provide another parameter of stealth contributing to the acute symptoms of plague.

It is now evident that bulk vegetative protein is not synthesized by pCD⁺ yersiniae under conditions of strict bacteriostasis imposed by the LCR, although marked expression of Yops and LcrV occurs in Ca^{2+} -deficient media. This relationship is consistent with the possibility that at least one LcrF-activated function promotes an as

yet undefined lesion in bioenergetics accounting for bacteriostasis. Virulence effectors encoded on the chromosome, pMT and pPCP also are produced in this environment during bacteriostasis including Caf1, Psa, KatY, Pla and murine toxin (as well as the ubiquitous chaperone GroEL; Mehigh and Brubaker, 1993). This finding suggests that these activities may be regulated by mechanisms that are independent of those known to control transcription of proteins required for generation of cell mass. It may, therefore, be significant in this context that the KatY promoter contained three homologs to the consensus recognition sequence of pCD-encoded transcriptional activator LcrF (Garcia et al., 1999a). Despite the presence of these sequences, synthesis of KatY remains temperature-conditional in mutants lacking pCD (Crumpton and Davies, 1956), suggesting that a second LcrF-like transcriptional activator is encoded within the chromosome.

Genetics

Historical

The modern era of research on the genetics of virulence in yersiniae commenced in 1980 upon the discovery of pYV by (Zink et al., 1980). Nevertheless, the experimental system developed earlier by T. W. Burrows and colleagues first illustrated the utility of defining virulence factors on the basis of mutant phenotype (Burrows, 1960; Burrows, 1963; Burrows and Bacon, 1958). The modification of experimental methods suitable for genetic analysis of yersiniae has kept pace of those techniques developed for other members of the Enterobacteriaceae. Shared methods include the use of certain conjugative plasmids or bacteriophages that are unable to integrate or replicate in yersiniae (i.e., the sex factor F⁺, P1 and λ for mediating gene transfer). Protocols are available for induction and selection of auxotrophic mutants (Brubaker, 1970a). Studies employing standard methods of transposon and bacteriophage insertion mutagenesis have been instrumental in identifying genes encoding virulence effectors and regulators. Use of these techniques has provided assurance that plague bacilli possess typical mechanisms of DNA repair as judged by UV induction of the bacteriocin pesticin (Ben-Gurion and Hertman, 1958; Hu et al., 1972), effectiveness of radiomimetic agents in inducing mutations (Brubaker, 1970b), and isolation of RecA⁻ mutants (Hare and McDonough, 1999a). The three plasmids of *Y. pestis* can readily be obtained by standard techniques and transformed by electroporation (Perry and Fether-

ston, 1997). Utilization of ligand-fusion protein engineering has been especially useful in defining the relationship between immunity and repression of proinflammatory cytokines as defined under Disease (Anderson et al., 1996; Fields and Straley, 1999a; Leary et al., 1995; Motin et al., 1994; Motin et al., 1996; Schmidt et al., 1999; Welkos et al., 1998).

The Genome

A genome of 4,208.4 kb was determined for *Y. pestis* strain KIM10 by two-dimensional pulsed-field gel electrophoresis of chromosomal DNA first digested with *Spe*I and then *Apa*I (Lucier and Brubaker, 1992). Addition of 9.7, 70.5 and 100.9 kb obtained by sequencing pPCP1, pCD1 and pMT1, respectively (Hu et al., 1998; Lindler et al., 1998; Perry et al., 1998), yields a total genome of 4,389.5 kb. This value is about 90% of that reported for *E. coli*. Extensive regions of the chromosome also have been sequenced (*Yersinia pestis* Sequencing Group, on-line) including the deletable *pgm* locus (Buchrieser et al., 1999) and the region encompassing *katY* (Garcia et al., 1999b). As noted under Phylogeny, almost 0.1% of the total genome consists of up to 50 copies of insertion sequence (IS) elements, which both diminish coding capacity and facilitate deletion as first shown for the *pgm* locus (Fetherston and Perry, 1994; Fetherston et al., 1992).

The *pgm* Locus

Genetic analysis of the *pgm* locus has provided definitive information regarding the stability of the genome and consequences of reciprocal recombination promoted by proximal IS elements. The possibility that the chromosome undergoes rapid internal rearrangement was raised by Iteman et al. (1993) who detected Hms⁻ mutants of laboratory strains that retained *irp2* within the high-pathogenicity island, although the reciprocal was not observed. Loss of the Hms⁺ phenotype in these strains was attributed in part to smaller deletions encompassing all or portions of the Hms region or to point mutations therein (Buchrieser et al., 1998b). This observation was inconsistent with the earlier report that the genome of *Y. pestis* is stable as judged by repeatable generation of precise DNA fragments by restriction enzyme digestion, and with the report that high-frequency mutation to Pgm⁻ was accompanied without exception by loss of an identical ~100-kb sequence (Lucier and Brubaker, 1992). The concept of an unstable genome in *Y. pestis* also is inconsistent with the observations that the *pgm* locus undergoes precise elimination by reciprocal recombination (Fetherston and Perry, 1994; Fetherston et al.,

1992) and that only Pgm⁺ isolates (containing *psn*) but lacking pPCP (encoding the pesticin immunity protein) are sensitive to pesticin (Brubaker, 1970a).

Selection for insensitivity to pesticin would be expected to yield rare Psn⁻ mutants (unable to assimilate yersiniabactin) entirely analogous to variants of *E. coli* resistant to group B colicins (Davis and Reeves, 1975). Mutation to Pgm⁻ does, of course, result in loss of the high-pathogenicity island (encoding the synthesis and assimilation of yersiniabactin) within which *psn* resides (Bearden et al., 1997; Buchrieser et al., 1998b; Buchrieser et al., 1999; Fetherston et al., 1995; Rakin et al., 1994). However, to select for the rare occurrence of point mutations within *psn*, it became necessary to score for insensitivity to pesticin plus retention of the *hms* locus (as judged by ability to autoagglutinate at room temperature). Cells of one such isolate retained the ability to absorb exogenous hemin or Congo red at 26°C. However, like typical Pgm⁻ mutants, these cells were unable to sustain growth at 37°C in iron-deficient medium (Sikkema and Brubaker, 1989). Analysis of this variant revealed that it possessed a 5-bp deletion (GACCT) in *psn*, causing premature termination of translation. This sequence occurred immediately after another GACCT run, thus its removal probably reflects a rare error in DNA replication (Lucier et al., 1996).

These findings illustrate that it is difficult to select for the occurrence of individual mutations in genes comprising the *pgm* locus due to spontaneous loss of the locus at high frequency. This point was emphasized by Hare and McDonough (1999a) who verified that pesticin-resistant mutants of a RecA⁺ Pgm⁺ strain of *Y. pestis* (cured of pPCP) arise at very high frequency and lack the entire *pgm* locus. Arising in an isogenic RecA⁻ isolate at a lower frequency, which would prohibit their detection in a RecA⁺ background, Hms⁻ mutants usually retained at least portions of the high-pathogenicity island. The RecA⁻ isolate also yielded rare pesticin-resistant mutants that were typically Hms⁺ (Hare and McDonough, 1999a). It is probably significant that the KIM strain was used in these experiments verifying that the high-frequency mutation to Pgm⁻ reflects reciprocal recombination between IS elements and that the genome is otherwise stable. As noted by Hare and McDonough (1999a), isolates found to undergo alternative mutational events resulting in high frequency acquisition of the Hms⁻ phenotype (Buchrieser et al., 1998b; Itean et al., 1993) represent laboratory stocks that may have accumulated additional IS elements or homologous sequences within the *pgm* locus during storage. This difference between strain KIM and laboratory stocks emphasizes the necessity of utilizing

isogenic derivatives of virulent isolates in defining parameters of pathogenesis.

Epidemiology

As noted under Phylogeny, *Y. pestis* is an exception to the epidemiological tenet of Theobald Smith (Smith, 1934) that states it is a flawed strategy for a parasite to unduly damage its host because by so doing that parasite compromises the only environment capable of supporting its existence in nature. The rationale for this anomaly is that death of the current host assures departure of the flea vector in search of a new host, thereby perpetuating plague bacilli in nature. The pathogens comprising this errant group are few, but like *Bacillus anthracis* (which must kill its host to assure efficient conversion to infectious spores), they rank among the deadliest known to humans.

Plague bacilli are newcomers in geological terms (Achtman et al., 1999); thus, insufficient time has elapsed since their emergence as a species to permit extensive clonal divergence. Nevertheless, limited but stable differences in electropherogram polymorphism occur among typical strains (Lucier and Brubaker, 1992) that should provide useful epidemiological markers. Similarly, phenotypic differences in the ability to ferment glycerol and reduce nitrite have proven useful in distinguishing between strains thought to be responsible for the three pandemics of history (Devignat, 1951). Isolates capable of both functions are of the biovar *antiqua*, believed to remain as holdovers from the first pandemic starting with the Justinian plague of the 6th century. Strains only able to ferment glycerol represent the biovar *medievalis* accountable for the second pandemic of Europe initiated during the 14th century by the Black Death. The biovar *orientalis* consists of isolates lacking both activities; these strains are responsible for the third pandemic of modern times. The legitimacy of this schema was underscored by the discovery of other genes encoded by the *pgm* locus that have undergone analogous sequential loss (Buchrieser et al., 1999). Similarly, Popov et al. (1998) demonstrated the occurrence of inversions resulting in differences of 3 kb in size between pMT from strains of the *antiqua* and *orientalis* biovars.

The three biovars noted above represent clones that have escaped confinement within the ancient plague reservoirs of the Russian steppes, central China and Mongolia. Less is known about the genetic makeup of *Pestoides* isolates or other strains resident to these areas, but local lore pronounces that strains recovered within some locations are attenuated, whereas those

from other regions are of extraordinary virulence. Similarly, variants possessing plasmids of distinct size or number have been isolated within these very old foci where the species probably emerged. One possibility that has received consideration in this context is that plague bacilli native to these regions may possess different genomic configurations than do the epidemic biovars of Devignat (1951). If so, the endemic forms would nevertheless remain capable of reciprocal recombination between IS elements, and thus be able to undergo almost unlimited chromosomal rearrangement via internal transposition and inversion, including return to the epidemic form (accounting for the occurrence of pandemics every 700 years or so). Further study of strains indigenous to the ancient plague reservoirs of central Asia will be required to substantiate this notion of a plastic genome.

Disease

It is generally trivial to demonstrate by genetic analysis that a given gene or product thereof is necessary for expression of virulence (although study of *Y. pestis* mutants also has repeatedly shown that determinants thought to be critical are dispensable and vice versa). It is altogether another matter to correctly identify how an essential determinant actually mediates disease. Before considering these issues, a description of experimental plague in mice will be provided and compared to the human disease. This exercise will emphasize unique features of the infection and facilitate later assignment of function to known effectors of virulence.

Pathology of Plague

As noted under Phylogeny, the remarkable ability of wild-type *Y. pestis* to cause lethal disease via peripheral (intradermal, subcutaneous or intraperitoneal) routes of infection is not shared by *Y. pseudotuberculosis* (Brubaker et al., 1965), although both species are of comparable high virulence when injected intravenously (Table 3). This distinction between routes of administration occurs because, as first shown in guinea pigs (Janssen et al., 1958), intravenously injected yersiniae undergo immediate removal from the vascular system upon passage through liver and spleen. This form of clearance is mediated by physical sieving within capillary beds, as well as phagocytosis by fixed macrophages (Janssen et al., 1958). Following filtration from the circulation, both of these facultative intracellular parasites soon emerge within interstitial spaces to form localized extracellular foci of infection (Nakajima et al., 1995; Simonet et al., 1990;

Straley and Cibull, 1989; Une et al., 1986). This sequence does not occur following peripheral administration where the enteropathogenic species are typically immobilized and eliminated at the original site of infection. In contrast, peripherally injected cells of *Y. pestis* possess a unique ability to invade adjacent tissues and eventually access favored niches within the viscera (Brubaker et al., 1965; Sodeinde et al., 1992; Welkos et al., 1997).

The mammalian host responds to bacterial invasion or the insult of injected foreign matter by promptly upregulating major proinflammatory cytokines. Especially important mediators of this generic inflammatory response are IFN- γ and TNF- α , known to fill indispensable roles in nonspecifically activating professional phagocytes and mediating formation of protective granulomas. Cells of *Y. pestis* lacking pCD resembled those of *E. coli* or other common bacteria in this regard as judged by their ability to promptly induce IFN- γ and TNF- α upon intravenous injection into mice (Fig. 6A). However, intravenously injected yersiniae harboring pCD downregulated expression of IFN- γ throughout the course of disease, although some TNF- α was produced after the mice had become moribund (Fig. 6B). This astonishing ability of pCD to abrogate inflammation could be reversed by priming the mice with trace levels of IFN- γ plus TNF α before infection (Fig. 6C) or by passive immunization with a polyclonal antiserum raised against pCD-encoded LcrV (Fig. 6D), whereupon the mice survived the infection (Nakajima and Brubaker, 1993). Wild-type cells of *Y. pestis* thus possess the truly remarkable faculty of preventing the generic inflammatory response necessary for eventual development of delayed-type hypersensitivity. This finding illustrates that the ability of *Y. pestis* to cause death does not reflect successful invasion of the host by frontal assault. Instead, lethality reflects an ability to disguise ongoing mortal tissue destruction, thereby maintaining the illusion that the host has no cause for alarm. In short, plague is a disease of stealth.

After accessing the viscera (either indirectly via lymphatic vessels and solid tissue or directly by intravenous injection), pCD⁺ yersiniae assume residence and commence multiplication in spleen and liver (Fig. 7). Thereafter, the lungs are invaded and replication progresses until organ function is lost and the mouse becomes moribund. By this time, significant net accumulation of bacteria occurs within the vascular system, thereby assuring infection of resident fleas that now partake of their last blood meal before departing in search of a new host. Intravenously injected yersiniae lacking pCD are similarly filtered from liver and spleen where they initiate growth in a manner similar to pCD⁺ organisms.

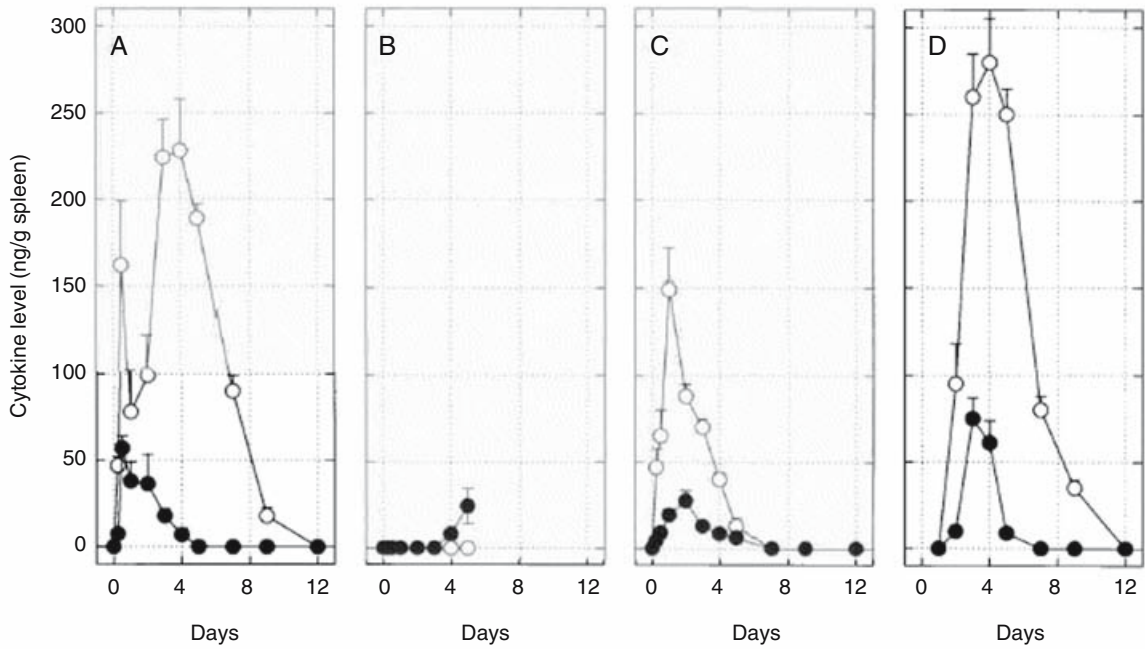

Fig. 6. Expression of the proinflammatory cytokines IFN- γ (○) and TNF- α (●) in C57/BL/6 mouse spleen following intravenous challenge with (A), 10^6 pCD $^-$ cells of *Y. pestis* KIM10; (B), 10^2 pCD $^+$ cells of *Y. pestis* KIM10; (C), 10^2 pCD $^+$ cells of *Y. pestis* KIM10 after priming with 20 μ g of IFN- γ and 20 ng of TNF- α □ and (D), 10^2 pCD $^+$ cells of *Y. pestis* KIM10 upon passive immunization on postinfection day 1 with 100 μ g of γ polyclonal rabbit anti-LcrV. All untreated mice challenged with pCD $^-$ yersiniae died by postinfection day 6 (B) whereas the remainder all survived. Redrawn from Nakajima and Brubaker (1993) and Nakajima et al. (1995).

Fig. 7. Growth of pCD $^+$ (●) and pCD $^-$ (○) *Y. pestis* KIM10, pYV $^+$ (■) and pYV $^-$ (□) *Y. pseudotuberculosis* PB1, and pYV $^+$ (▲) and pYV $^-$ (△) *Y. enterocolitica* WA in mouse spleen, liver, lung and blood following intravenous injection of 10^2 pCD/pYV $^+$ yersiniae and 10^4 pCD/pYV $^-$ mutants (T. Une and R. Brubaker, unpublished observations).

However, proliferation soon ceases within these foci and the bacteria become eliminated without reentering the vascular system (Nakajima et al., 1995; Une et al., 1986).

Predominant extracellular growth of *Y. pseudotuberculosis* in visceral organs was first reported by Simonet et al. (1990). Inspection of thin sections from liver and spleen revealed that pCD⁺ isolates of *Y. pestis* also grew extracellularly within enclosed non-vascularized necrotic foci (Nakajima et al., 1995; Une et al., 1986). These necrotic lesions progressively enlarged and then coalesced as the infection continued (Fig. 8A). At no time did the host mount a detectable inflammatory response against the bacteria contained within these foci, which eventually hemorrhaged resulting in spillover into the vascular system. Like the pCD⁺ parent, intravenously injected pCD⁻ yersiniae also assumed residence within interstitial spaces of visceral organs, but the resulting lesions were almost immediately surrounded by inflammatory cells that promptly facilitated formation of protective granulomas (Fig. 8B). Throughout the course of disease, bulk vegetative growth occurred almost exclusively within spleen, liver and then lung (Fig. 7). These organs became literally consumed and were almost stoichiometrically converted to bacterial mass. Because bulk vegetative growth occurs primarily within cytoplasm released into closed necrotic foci, the ability to resist uptake by neutrophils and monocytes is of minimal

importance as a mechanism preventing acute disease. Reliance upon liver and spleen as favored niches for bulk vegetative growth does not, of course, preclude a role for professional phagocytes in delaying invasion of the viscera following peripheral administration or upon infection of the dermis by fleabite. The terminal population of intravenously injected enteropathogenic yersiniae in moribund mice is typically about ten times that observed for *Y. pestis* which, at comparable challenge doses, also causes an earlier death (Fig. 7). As noted under Physiology, this distinction between *Y. pestis* and *Y. pseudotuberculosis* may reflect, in part, the lethal action of pMT-encoded murine toxin.

The succession of events in human plague is similar to those observed in the mouse and many other rodents, except that these natural hosts usually expire before comparable lymphadenopathy can develop. Typical symptoms of untreated plague in humans include pronounced fever, headache and local edema accompanied by tenderness of the regional lymph nodes draining the extremity receiving the infecting fleabite. These (cervical, femoral/inguinal or axillary) lesions are termed “buboes”; they delay but generally fail to prevent eventual invasion and colonization of the viscera in a manner analogous to that described in the mouse. Indeed, removal of the invading bacteria by filtration within regional lymph nodes may sometimes fail entirely, thereby facilitating bacteremia and visceral inva-

Fig. 8. Characteristic histopathological changes in liver caused by *Y. pestis* KIM10 on postinfection day 3. Hematoxylin and eosin stain was used. (A) Control mouse infected with pCD⁺ yersiniae shows multiple necrotic focal lesions without inflammatory cell response (magnification, $\times 140$); (B) Control mouse infected with pCD⁻ yersiniae exhibits granuloma formation (magnification, $\times 280$); (C) Mouse actively immunized with PAV and infected with pCD⁺ yersiniae shows protective granulomatous lesions (magnification, $\times 140$); and (D) Mouse passively immunized with polyclonal rabbit anti-PAV and infected with pCD⁺ yersiniae shows pre-granulomatous lesions prompting infiltration of inflammatory (mononuclear) cells (magnification, $\times 70$). From Nakajima et al. (1995).

sion. This type of disease, termed “septicemic plague,” is noted for a higher mortality rate (~90%) than the more typical bubonic form (~50%). Marked bacteremia also is characteristic of the final phase of bubonic plague. This symptom is ominous and generally reflects terminal colonization of liver and spleen. Another unfortunate and almost uniformly lethal variation of the human disease is pneumonic plague characterized by fever, cough and chest pain. The appearance of pneumonic plague during an epidemic is especially portentous because this variation of the disease permits direct transfer without reliance on the flea vector.

It sometimes has been suggested that the plague bacillus is now attenuated and no longer the scourge responsible for the Black Death. This notion was aptly challenged by Thomas Butler (Butler, 1983) who, as an isolated physician during the conflict in Vietnam, stated “... we were humbled by the swift progression of this disease that carried healthy individuals to death within three days.” One citation in Butler’s treatise noted that pneumonic plague in humans remains so severe that individuals may become ill and die on the same day they were infected. Antibiotics, however, can cure even this form of the disease if therapy is initiated promptly after exposure (Butler, 1983).

Immunity

Both humoral and cellular mechanisms of immunity can provide protection against plague. Indeed, the disease is a race between the ability of the bacteria to cause death and the capacity of the host to mount a successful immune response. This contest is seldom won by the infected rodents (and often lost by humans), thus an appreciation of protective antigens is essential in understanding the nature of tissue invasion versus bulk vegetative growth in the viscera.

Cell-Mediated Immunity

A live vaccine consisting of pCD⁺, Pgm⁻ cells of *Y. pestis* EV76 provides effective immunity against plague. Carriage of pCD, however, is not necessary for protection by live cells, indicating that antigens other than those encoded by this plasmid are immunogenic (Burrows, 1963). Simonet et al. (1985a) showed that live pYV⁻ cells of *Y. pseudotuberculosis* could also immunize against plague, thereby eliminating not only functions of pCD/pYV but also pPCP⁻ and pMT⁻ encoded activities as sole protective antigens. Though these results may reflect, in part, a contribution by circulating antibody, they also are in accord with the findings of Wong and Elberg (1977), who first demonstrated that fractions

of *Y. pestis* could initiate a classical T cell-modulated state of cellular immunity. It is now accepted that cell-mediated processes can provide significant protection against plague. Indeed, the ability to form protective granulomas, the hallmark of delayed-type sensitivity, assures the defeat of pathogenic yersiniae. However, preparations capable of promptly eliciting an effective cell-mediated response consist of whole bacteria or particulate matter and thus are apt to promote untoward inflammatory reactions. Consequently, investigators concerned with developing modern vaccines have concentrated on atoxic soluble subunit antigens possessing the ability to raise protective circulating antibodies.

Humoral Immunity

A partially purified preparation of Caf1 generated protective antibodies against *Y. pestis* in mice (Baker et al., 1952); this and other reports in the early literature defining the ability of Caf1 to immunize against plague were reviewed by Burrows (1963). As already noted, Caf1 is not essential for lethality in mice (Burrows, 1957), monkeys (Davis et al., 1996) and probably humans (Winter et al., 1960). It is, therefore, not surprising that the degree of protection obtained upon immunization with Caf1 is modest (Andrews et al., 1996; Burrows, 1963; Meyer et al., 1974; Welkos et al., 1995), at least in comparison to that provided by LcrV (described below), which is known to be essential for expression of virulence. The ineffectiveness of Caf1 as a vaccine is heightened by the observation, first made by Burrows (1957), that Caf1⁻ mutants constitute the terminal population of yersiniae recovered from mice succumbing to challenge with Caf1⁺ *Y. pestis* after immunization with Caf1. Mutation to Caf1⁻ was reported to occur at high frequency both in vitro and in vivo (Burrows and Bacon, 1958; Drozdov et al., 1995; Pirt et al., 1961), thus emphasizing its limitations as a soluble vaccine and determinative target for rapid identification.

The LcrV is superior to Caf1 determinant as a protective antigen as judged by its greater protective index and utter necessity as an effector of virulence (thereby eliminating the possibility of overgrowth by LcrV⁻ mutants in vivo as occurs with Caf1⁻ mutants). Results of initial studies showed that mice immunized with Lcr⁺ strains generally exhibited greater immunity to subsequent challenge with wild-type yersiniae than occurred after immunization with Lcr⁻ isolates (Burrows and Bacon, 1958). This observation was extended by Lawton et al. (1963) who showed that rabbit antiserum raised against a partially purified preparation of LcrV provided passive protection against plague in mice.

Attempts to prepare homogenous native LcrV by traditional methods of biochemical fractionation were unsuccessful due to the penchant of this protein to degrade spontaneously (Brubaker et al., 1987). Nevertheless, rabbit antisera prepared against the resulting mixture of highly purified peptides also provided passive immunity (Une and Brubaker, 1984a), allaying criticism that the active component present in the preparation of Lawton et al. (1963) was actually one or more contaminating antigens. More convincing evidence that anti-LcrV is protective was provided by Motin et al. (1994) who engineered a construct encoding a staphylococcal Protein A-LcrV fusion protein termed "PAV." After expression in *E. coli* and purification by affinity chromatography, homogenous PAV was used to immunize rabbits; the resulting antiserum provided significant passive protection against plague. Formal proof that immunity was, indeed, caused by anti-LcrV was provided by demonstrating that absorption of anti-PAV with excess native LcrV (or engineered truncated derivatives) eliminated the serum's ability to passively protect against disease. These experiments showed that at least one major protective epitope resided between amino acids 168 and 275. Protein A-LcrV fusion protein (PAV) was found to actively immunize against an intravenous challenge of $\sim 10^4$ pCD⁺ cells of *Y. pestis* (Nakajima et al., 1995), whereas a homogenous preparation of hexahistidine-LcrV fusion protein (V_h) purified by nickel affinity chromatography provided similar protection against $\sim 10^7$ bacteria (Motin et al., 1996). These observations have been amply verified and extended to provide the basis for an effective subunit plague vaccine consisting of LcrV alone (Anderson et al., 1996; Carr et al., 1999; Hill et al., 1997; Leary et al., 1995; Pullen et al., 1998) or in combination with CafI (Heath et al., 1997; Spiers et al., 1999; Williamson et al., 1999). In related studies, the LcrV homolog of *Pseudomonas aeruginosa* (PcrV) also was found to serve as a protective antigen (Sawa et al., 1999).

As noted above and under Physiology, loss of *lcrV* is pleiotropic in that these mutants fail to express or secrete effector Yops. Anti-LcrV could therefore provide immunity by mechanically blocking the type III translocation apparatus as reported for anti-PcrV in *Pseudomonas* (Sawa et al., 1999). In this case, other surface components of the secretion machine also might be expected to provide protection. Although the expression of Yops by *Y. pestis* in vitro is cryptic (Chalvignac et al., 1988; Kuttyrev et al., 1999; Mehig and Brubaker, 1993; Mehig et al., 1989; Sample and Brubaker, 1987a; Sample et al., 1987b; Straley and Brubaker, 1981; Straley and Brubaker, 1982), these proteins are clearly pro-

duced in vivo as first demonstrated by the presence of corresponding antibodies in convalescent human sera (Mazza et al., 1985). Anti-Yops antibodies also were observed upon study of mice surviving infection by aerosol following antibiotic therapy (Benner et al., 1999). Nevertheless, active immunization with the virulence effectors YopE and YopH or components of the secretion machine (YopK or LcrE) failed to provide significant protection (Andrews et al., 1999; Leary et al., 1999); YopD immunized against modest challenge with $\sim 2 \times 10^3$ yersiniae (Andrews et al., 1999). It is not surprising that antibodies directed against effector Yops fail to provide significant protection because the type III secretion apparatus effectively compartmentalizes these proteins from the immune system. However, it is not yet resolved why components of the secretion machine, itself, other than LcrV, fail to raise effective protective antibodies. One prospect is that, of the constituent proteins so far examined, only LcrV is accessible to antibodies. Another possibility is that the major physiological role of cytotoxic Yops is to promote focal tissue necrosis as shown in Fig. 7 and these non-vascularized lesions are inaccessible to circulating antibodies. Alternatively, LcrV might mediate a second unique function elsewhere required for virulence and neutralizable by circulating antibody. An observation favoring the latter alternative is that anti-LcrV restores the ability of the host to mount a generic inflammatory response (Fig. 6D) characterized by normal expression of IFN- γ and TNF- α (Nakajima and Brubaker, 1993).

Pettersson et al. (1999) presented data indicating that LcrV appears on the bacterial surface before contact with the host target cell and that its interaction with specific antibody blocks subsequent translocation of effector Yops. Unfortunately, these results could not be verified by Fields et al. (1999b) who also observed the presence of LcrV in punctate zones on the bacterial surface but found that an otherwise protective anti-LcrV serum failed to inhibit pCD-mediated translocation of YopE by docked yersiniae. As noted below, the ability to express IFN- γ and TNF- α as a function of stress was prevented by recombinant LcrV (Nakajima et al., 1995). Downregulation of these important proinflammatory cytokines by recombinant LcrV also was detected in cell culture (Schmidt et al., 1999). Evidence is summarized below indicating that the ability of anti-LcrV serum to provide immunity reflects its ability to restore the generic inflammatory response. Additional antigens capable of raising protective antibodies against plague undoubtedly exist. For example, anti-Pla serum was found to provide passive immunity against subcutaneous infection presumably by

preventing plasmin-mediated metastasis of invading yersiniae (Kutyrev and Brubaker, 1999).

Virulence Factors Required for Dissemination in Tissues

Studies of the disease process outlined immediately above demonstrated that plague bacilli first access favored sites of multiplication within the viscera from dermis and then commence a massive and prolonged process of vegetative growth. This second phase seriously jeopardizes host homeostasis by causing eventual loss of organ function accompanied by spillage of the organisms into the vascular system. Determinants of virulence that facilitate the first invasive phase of plague are not always involved in the second vegetative phase and vice versa. Furthermore, cells of *Y. pestis*, as well as the enteropathogenic yersiniae, can cause acute disease following intravenous injection but only plague bacilli possess the ability to efficiently access internal organs from the peripheral sites of infection. This journey is tumultuous as judged by the larger inocula of enteropathogenic yersiniae required to cause death by subcutaneous or intradermal administration (Table 3). Obviously plague bacilli easily foil nonspecific processes of host defense that waylay enteropathogenic yersiniae en route. Indeed, it is the virulence factors of the first invasive phase that largely account for the acute nature of bubonic plague.

Yersiniae pathogenic to humans, like most Gram-negative bacterial pathogens, are innately indifferent to lysozyme and β -lysin. Cells of *Y. pseudotuberculosis* grown at 37°C are resistant to complement-mediated killing, whereas those cultivated at 26°C are sensitive; this property is constitutive in *Y. pestis* (Une and Brubaker, 1984b). Similarly, smooth LPS is elaborated by cells of *Y. pseudotuberculosis* grown at 26°C that possesses O-group structures containing immunodominant 3,6-dideoxyhexoses (Samuelsson et al., 1974). These O-groups are not formed during growth at host temperature and an analogous rough LPS is constitutively expressed by plague bacilli (Federova and Devdariani, 1998; Minka and Bruneteau, 1998; Porat et al., 1995). Liposomes composed of rough LPS from these two species were resistant to complement-mediated lysis, whereas those formed from the smooth LPS of *Y. pseudotuberculosis* grown at 26°C were sensitive (Porat et al., 1995). This result was not dependent upon carriage of pCD/pYV, although only pYV⁺ cells of *Y. enterocolitica* grown at 37°C (and liposomes prepared with LPS from these bacteria) were resistant to complement (Porat et al., 1995; Une and Brubaker, 1984a). The pYV-encoded YadA adhesin of the enteropathogenic

yersiniae was reported to prevent complement-mediated killing (Finlay and Falkow, 1997) but probably does not account for serum-resistance of liposomes. In any event, neither YadA nor invasins are expressed by *Y. pestis*, leaving no other alternative at present but to assign serum-resistance of this species to rough LPS structure.

Considerable controversy surrounds the ability of yersiniae pathogenic to humans to avoid uptake by professional phagocytes or to survive intracellularly following this event. Reports of studies comparing these abilities in *Y. pestis* and the enteropathogenic yersiniae under identical conditions have not yet appeared; thus, results obtained with one species may not apply to another. Once ingested by professional phagocytes, cells of *Y. enterocolitica* cured of pYV fare poorly, emphasizing the importance of pYV-mediated functions in promoting resistance to intracellular killing (Hartland et al., 1996; Hartland et al., 1994; Lian and Pai, 1985; Ruckdeschel et al., 1996). However, pYV⁻ cells of *Y. pseudotuberculosis* grew as rapidly within primary macrophages of spleen and kidney as did those of the pYV⁺ parent (Richardson and Harkness, 1970). In contrast, Simonet et al. (1985b) demonstrated that carriage of pYV by *Y. pseudotuberculosis* neither facilitated resistance to ingestion by mouse resident macrophages in vitro nor inhibited the oxidative burst of macrophages. Extension of this approach to the early stages of infection in mice showed that both pYV⁺ and pYV⁻ organisms were eliminated at equal rates from the liver and the peritoneal cavity. This finding suggested that pYV-mediated factors were either not effective in preventing intracellular killing or not expressed until after a significant latent period. Phagocytosis of pYV⁺ cells of *Y. pseudotuberculosis* by a monocyte-macrophage cell line (J774A.1) resulted in normal degranulation and formation of phagolysosomes within which the bacteria were killed (Mills et al., 1997). *Salmonellae*, but not *E. coli*, not only survived this ordeal but also increased five-fold in number during the process. The Caf1 antigen of *Y. pestis* confers modest resistance to uptake by professional phagocytes, especially neutrophils and monocytes, during the initial invasion of tissues. However, this capsular antigen probably is ineffective against fixed macrophages lining the capillary network of liver and spleen as judged by the ability of both Caf1⁺ and Caf1⁻ strains to initiate growth in these organs following intravenous injection. Both pCD⁺ and pCD⁻ plague bacilli survived equally well within free macrophages, at least at low multiplicities (Cavanaugh and Randall, 1959; Charnetzky and Shuford, 1985; Goguen et al., 1986; Janssen and Surgalla, 1969; Straley and Harmon, 1984). These observations suggest that pCD/pYV-mediated

functions are insufficient for survival of *Y. pseudotuberculosis* in free phagocytes and superfluous for such survival of *Y. pestis*. Further work will be necessary to verify the impression that carriage of pCD/pYV is unnecessary for rapid growth of *Y. pestis* and *Y. pseudotuberculosis* within fixed macrophages.

Even though effector Yops do not mediate intracellular survival of *Y. pseudotuberculosis* or *Y. pestis*, their translocation can render professional phagocytes incapable of ingestion (Anderson et al., 1999; Fallman et al., 1995; Persson et al., 1997; Persson et al., 1995; Rosqvist et al., 1990) or cause them to undergo apoptosis (Mills et al., 1997; Monack et al., 1998; Monack et al., 1997; Ruckdeschel et al., 1997). Nevertheless, it is only at higher multiplicities that pCD-mediated cytotoxic Yops assure prompt destruction of professional and nonprofessional phagocytes (Charnetzky and Shuford, 1985; Goguen et al., 1986). Considered in this sense, these effectors are correctly viewed as leukocidins. However, plague bacilli may not achieve multiplicities sufficiently high to destroy professional phagocytes during migration from peripheral sites of infection to visceral organs except during invasion of regional lymph nodes. This confrontation prompts cytolysis and tissue destruction leading to formation of buboes. The organisms are otherwise viewed with seeming indifference by the host and, upon arrival at their destination in visceral organs, proceed to initiate bulk vegetative growth within focal necrotic lesions. Further study will be necessary to define the basis of this prompt and safe passage. The absence of YadA, Inv and Ail minimizes bacterial interaction with both professional and nonprofessional phagocytes. This deficiency thus hastens the journey while reducing expression of proinflammatory cytokines/chemotaxins induced by contact with host cells.

Two additional determinants are required for successful invasion of the viscera. As shown in Table 3, the first is pPCP-encoded Pla and the second is the ability to express the siderophore yersiniabactin encoded by genes resident to the high-pathogenicity island mapping within the *pgm* locus (described under Physiology). The simplest explanation for the requirement of Pla is that this outer-membrane tissue invasin promotes adherence to the mammalian extracellular matrix, thereby facilitating bacterial metastasis (Lähtenmäki et al., 1998). The finding that mutation to *Pgm*⁻ (and thus loss of ability to synthesize yersiniabactin) also is necessary for invasion probably indicates that iron is in especially short supply in peripheral tissue and cannot be adequately assimilated without use of this high-affinity mechanism of transport. Further study will be required to determine whether KatY,

indeed, functions as a virulence factor as might be anticipated by its abundant temperature-dependent production and, if so, whether this activity facilitates survival within professional phagocytes or serves some alternative function.

Virulence Factors Required for Vegetative Growth in Visceral Organs

The comparisons between the pathology of murine and human plague outlined above provide three insights. First, the diseases in both hosts are similar except that the mouse succumbs before exhibiting comparable lymphadenopathy. Second, death occurs only after the bacteria have undergone numerous doublings in visceral organs. Third, the ability of all yersiniae (pathogenic to humans) to sustain this assault is dependent upon carriage of pCD/pYV as shown by the observation that mutants lacking these plasmids (or lacking certain genes encoded thereon) are rapidly cleared from liver and spleen (Fig. 7). This vegetative phase of the disease involves the destruction of tissue comprising these organs and subsequent metabolism of nutrients within the released cytoplasm. Cell disintegration is probably accomplished exclusively by the pCD-encoded type III protein secretion system described under Physiology that translocates cytotoxic Yops from the cytoplasm of docked yersiniae into target nonprofessional phagocytes. This process functions without exposing the virulence effectors to the extracellular environment and is tightly regulated by temperature, metallic cations, and ability to form an intact structural unit required for translocation. The remarkable feature of this mechanism is that the host permits it to occur. Tissue damage of this extent invariably causes inflammation accompanied by release of chemotaxins and proinflammatory cytokines that lead to prompt infiltration of mononuclear cells capable of containing the invading bacteria within protective granulomas. Formation of granulomas is the last nonspecific resort of the host in defending against bacterial invasion. However, containment within granulomatous lesions is extraordinarily effective in that physiological changes within the enclosed environment are extreme and highly bactericidal as might be expected of a process used to control infection caused by many facultative intracellular parasites. In short, cells of *Y. pestis* lacking pCD promptly undergo containment and then destruction within granulomas during residence in visceral organs. However, carriage of pCD both facilitates tissue necrosis and prevents infiltration of inflammatory cells, thereby assuring unrestricted growth (Nakajima et al., 1995; Une et al., 1986).

The LcrV protein inhibits normal production of IFN- γ and TNF- α (Fig. 6) as judged by the

ability of anti-LcrV to restore the generic inflammatory response (Nakajima and Brubaker, 1993). Furthermore, an engineered staphylococcal Protein A-LcrV fusion protein termed PAV, expressed in *E. coli* and purified to homogeneity by IgG affinity chromatography (Motin et al., 1994), mimicked the ability of whole pCD⁺ yersiniae to downregulate IFN- γ and TNF- α (Nakajima et al., 1995). These results, shown in Fig. 9, strongly indicate that LcrV per se accounts for downregulation. Schmidt et al. (1999) showed that a LcrV-polyhistidine fusion protein engineered from *Y. enterocolitica* downregulated LPS-induced TNF- α in mouse spleen and liver. This inhibition occurred at the level of mRNA synthesis, was not associated with upregulation of interleukin-10, could be blocked by specific antibody in tissue culture, and was dependent upon the presence of both macrophages and activated T cells. Considered together, these results suggest that LcrV per se prevents the host from mounting an effective inflammatory response against plague bacilli. However, as noted above, others have suggested that translocated Yops, especially YopH and YopJ, also promote this effect (Mills et al., 1997; Monack et al., 1998; Palmer et al., 1998; Schesser et al., 1998; Yao et al., 1999). Though suppression of macrophage-induced TNF- α by YopJ is tenable, its mode of action would not be expected to downregulate IFN- γ , which is primarily expressed by T_H1 cells. Indeed, YopJ- mutants retain the ability to suppress IFN- γ and TNF- α in a manner identical to that shown in Fig. 6B for pCD⁺ yersiniae (R. Brubaker, unpublished observations). The YopH protein can modulate a wide variety of T and B cell-mediated responses by downregulating the co-stimulatory molecule B7.2 (Yao et al., 1999) and thus undoubtedly helps maintain the anti-

inflammatory umbrella typical of plague. Note, however, that docking of yersiniae to host cells is necessary for initiation of anti-inflammatory activities provided by YopH and YopJ; thus their effects will necessarily remain localized as opposed to that of LcrV which is active in extracellular soluble form (Motin et al., 1997; Nakajima et al., 1995; Nedialkov et al., 1997).

Whereas YopJ and YopH undoubtedly contribute to downregulation of IFN- γ and TNF- α , these and other Yop effectors also account for the pCD-mediated focal lesions of liver and spleen that are characteristic of infection by *Y. pestis* and *Y. pseudotuberculosis*. Tissue damage of this extent would not otherwise be tolerated by the host and would be promptly controlled by normal nonspecific processes assuring infiltration of inflammatory cells and subsequent formation of granulomatous lesions. However, owing to the ability of yersiniae to downregulate proinflammatory cytokines, the host is unable to initiate the steps necessary to provide effective containment. This bleak outlook is entirely in accord with the observation of Welkos et al. (1998) that LcrV blocks chemotaxis of neutrophils. Consequently, yersiniae progressively enlarge the focal lesions within which they are contained and eventually overwhelm organ function causing death. Subtle but probably significant differences exist between the focal necrotic lesions caused by plague bacilli within visceral organs and those formed by *Y. pseudotuberculosis* (Nakajima et al., 1995). The latter resemble abscesses in that they are surrounded by neutrophils, which nevertheless are ineffective in containing the infection. The explanation for this difference is unknown. One possibility is that the anti-inflammatory umbrella provided by LcrV for *Y. pseudotuberculosis* might be leaky. That is, either YadA/invasin-host cell interaction, extra-

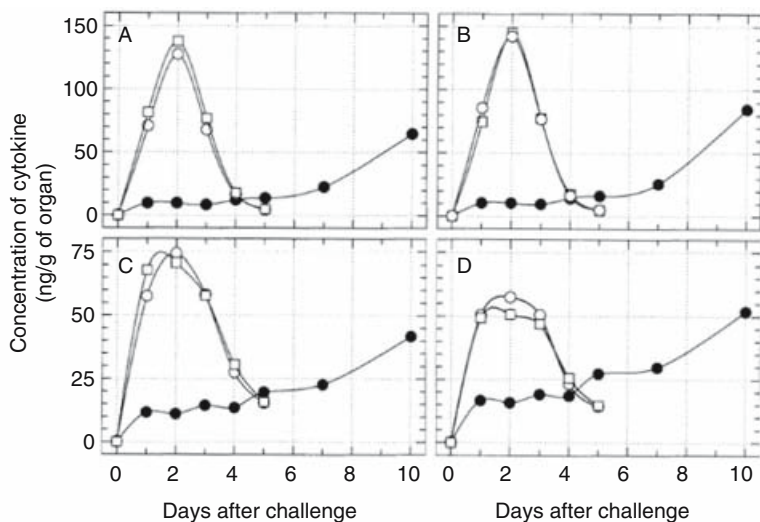

Fig. 9. Levels of IFN- γ in spleen (A) and liver (B) or of TNF- α in spleen (C) or liver (D) of outbred (Swiss-Webster) mice following induction of cytokine synthesis on day 0 by intravenous injection of 10^6 avirulent pCD⁻ cells of *Y. pestis* KIM. Mice received daily injections of 0.1 ml of 0.033 M potassium phosphate buffer, pH 7.0 (□), or 100 μ g of either Protein A (○) or Protein A-LcrV (PAV) fusion protein (●) in 0.1 ml of the same buffer on postinfection days 0 through 5. Values represent averages determined for four mice. Data from Nakajima et al. (1995).

cellular accumulation of undelivered Yops (expressed in the Ca^{2+} -deficient environment of released host cell cytoplasm), or both could provide sufficient stimulation to enable the host to overcome the anti-inflammatory effects of LcrV, YopJ and YopH. These events would constitute the basis for environmental pressure favoring the selection of mutants lacking YadA, Inv and Ail and furnish an additional advantage for expression of Pla.

Applications

Students of molecular pathogenesis are nowadays forewarned that new infectious diseases will almost surely arise and old afflictions such as the pestilence will re-emerge. These specters are very real, as is the threat that the old epidemic diseases of humans will appear again in even more sinister forms (agents of biological warfare and terrorism). To prevent or at least minimize these bleak scenarios, many governments presently sponsor laudable programs to design effective methods to identify highly pathogenic species and develop vaccines to prevent the diseases that they cause. The silver lining to the present focus on these onerous aspects of medical microbiology is that investigators are becoming increasingly aware that the gene pools of highly pathogenic species encode astonishing biological activities that possess the potential to reverse the pathology of noninfectious processes of disease. The LcrV protein is an excellent example of this phenomenon.

Perry et al. (1998) noted that LcrV is the only pCD-encoded virulence factor capable of mediating biological effects in soluble form from host fluids. These responses all reflect the penchant of this protein to downregulate proinflammatory cytokines (Nakajima et al., 1995; Schmidt et al., 1999) and thereby minimize inflammation. This effect, of course, is not always beneficial in that injected PAV significantly prolonged the retention of LcrV⁻ mutants in vivo and greatly enhanced the ability of unrelated bacteria (especially *Listeria monocytogenes*) to cause serious disease (Nakajima et al., 1995). Prolonged administration of PAV to normal mice did not, however, result in overgrowth by the normal flora. These determinations were undertaken to compare the retention of skin allografts in mice so as to distinguish pure anti-inflammatory activity resulting from downregulation of proinflammatory cytokines from inhibition of specific immunity (Motin et al., 1997). No significant difference was noted between treated and control mice with regard to time of total allograft retention, but the period before onset of visible inflammation was doubled from 6 to 12 days

($p < 0.001$). This finding illustrates that LcrV is indeed anti-inflammatory but does not interfere with the onset of specific cell-mediated immunity per se (other than inhibiting cytokine-mediated processes common to both mechanisms). It is established that endotoxic shock is a consequence of tissue damage resulting from excessive stimulation by proinflammatory cytokines. An LPS-free polyhistidine-tagged LcrV fusion protein (Motin et al., 1996) promoted an immediate resistance to LPS that rapidly dissipated and then reappeared after 48 hours (Nedialkov et al., 1997). Downregulation of IFN- γ and TNF- α occurred during both phases, as did eventual upregulation of anti-inflammatory cytokines, especially IL-10 (generally known to mediate LPS tolerance). The early phase of resistance could not represent LPS tolerance (which requires 48 hours for full expression); thus, immediate downregulation of IFN- γ and TNF- α appeared to reflect some novel LcrV-mediated ability to promptly upregulate anti-inflammatory cytokines, thereby preventing inflammation. The interpretation that LcrV functions by upregulating IL-10 is probably fallacious as judged by the finding of Schmidt et al. (1999) that anti-IL-10 did not influence the ability of LcrV to immediately downregulate IFN- γ and TNF- α (although upregulation of anti-inflammatory cytokines may still account for the delayed phase of resistance).

Any mechanism capable of inhibiting the expression of proinflammatory cytokines has obvious potential applications in the treatment of inflammatory diseases such as arthritis, rheumatism and septic shock. Although the ability of PAV to postpone (but not prevent) inflammation associated with allograft rejection was impressive, of equal interest was the observation that the grafts "set" immediately without exhibiting erythema, edema or other signs of inflammation, which suggests an application in the healing of wounds. Further study may show that Pla has similar applications in the treatment of noninfectious processes. The possibility that this protein can serve as an alternative to other plasminogen activators in the treatment of cardiovascular disease is obvious. However, the ability of Pla to generate plasmin at the level of the basement membrane and thereby promote bacterial metastasis by dissociating host cells is unique (Lähteenmäki et al., 1998). It will be interesting to see if this activity can similarly dissociate solid tumor cell masses, thereby facilitating normal chemotherapeutic regimens. It is entirely likely that these and other appropriately cloned and purified virulence factors of yersiniae, as well as analogues from other pathogenic species, will see widespread use as therapeutic agents in the near future.

Erwinia and Related Genera

CLARENCE I. KADO

Introduction

Members of the genus *Erwinia* are primarily plant-pathogenic and plant-associated bacteria. As modern approaches have focused on the direct analysis of genes and their gene products, commonly associated phenotypes such as the type of disease that they cause and the relatedness of rDNA have prompted splitting of certain *Erwinia* members into the genus *Enterobacter*, *Pectobacterium*, *Pantoea* or *Brenneria*. For example, the genus *Pectobacterium*, which was suggested previously (Brenner et al., 1973), has been resurrected to accommodate those species that profusely produce pectinolytic enzymes in plant pathogenesis and that have related rDNA (Hauben et al., 1998). Because of the large difference in the percent G+C and the rDNA sequence, the genus *Pantoea* was added. As the sequences of entire genomes of this group of organisms become available, regrouping of the members of these genera will likely take place. Pairwise 16S rDNA sequence comparisons also showed *E. alni*, *E. nigrifluens*, *E. paradisiaca*, *E. quercina*, *E. rubrifaciens* and *E. salicis* grouped into the new genus *Brenneria* (Hauben et al., 1998).

Erwinia

The genus *Erwinia* is classified in the *Enterobacteriaceae*. Most members of this genus characteristically cause diseases of plants. Recent 16S rDNA sequence comparisons have been proposed to delineate species originally classified in the genus *Erwinia* into the genus *Pantoea*, *Enterobacter*, *Pectobacterium*, or *Brenneria*. Certain species with the distinct glucose metabolism of oxidizing D-glucose into various forms of gluconate have been removed from the genus *Erwinia* and moved into the genus *Pantoea*. All of the genera possess the main phenotypic characteristics of the *Enterobacteriaceae*. They produce acid from sugars, are Gram-negative rods bearing peritrichous flagella, and can ferment

substrates anaerobically. The phylogenetic position of the genus *Erwinia*, along with other members of the *Enterobacteriaceae* associated with plants, have been explored using 16S rDNA nucleotide sequence comparisons (Kwon et al., 1997; Hauben et al., 1998). Four phylogenetic groups representing a branch of the lineage tree have been proposed. One group comprises *E. amylovora*, *E. rhapontici*, *E. persicina*, *E. psidii*, *E. pyrifoliae*, *E. mallotivora* and *E. tracheiphila*. The second group consists of *E. carotovora* subspecies, *E. chrysanthemi*, and *E. cypripedii*. The latter group was proposed to be moved to the genus *Pectobacterium* primarily because it produces pectolytic enzymes for pathogenesis (for history see Brenner et al., 1973). The third group comprises *E. alni*, *E. nigrifluens*, *E. rubrifaciens*, *E. paradisiaca*, *E. quercina*, and *E. salicis*. It was suggested this third group be moved into the proposed genus *Brenneria* (Hauben et al., 1998). The fourth group comprises members that display unusual oxidative metabolism of D-glucose and produce yellow to mauve colonies. They were reclassified into the genus *Pantoea* (Gavini et al., 1989; Kageyama et al., 1992; Mergaert et al., 1993). The generic positioning of *Enterobacter*, *Pectobacterium*, *Pantoea*, and *Brenneria* was essential to avoid further confusion in sorting species previously classified within the genus *Erwinia*. A more solid positioning will be forthcoming when the entire genome of each of these genera is completed and comparisons of each of the genomic sequences are made.

Habitat

Erwinia, *Enterobacter*, *Pectobacterium*, *Pantoea* and *Brenneria* species cause four basic types of plant diseases: 1) rapid necrosis; 2) progressive tissue maceration called “soft-rot;” 3) occlusion of vessel elements called “vascular wilt,” and 4) hypertrophy leading to gall or tumor formation. A list of species with these characteristic phenotypes is shown in Table 1.

Table 1. *Erwinia* and subspecific genera and their disease-causing types.

Species	Disease name	Type of infection	Natural host plant
Necrogenic group emended from <i>Erwinia</i> to <i>Brenneria</i> (Hauben et al., 1998)			
<i>Brenneria alni</i> Wilson et al., 1957	Canker	Necrogenic	Alder
<i>B. nigrifluens</i>	Shallow canker	Necrogenic	Members of the Juglandaceae
<i>B. paradisiaca</i>	Brown-black root rot	Necrogenic	Banana
<i>B. quercina</i> Hildebrand and Schroth, 1967	Drippy nut and blight	Maceration	Coast live oak (<i>Quercus agrifolia</i>)
<i>B. rubrifaciens</i> Wilson et al., 1967	Deep bark canker	Necrogenic	Members of the Juglandaceae
<i>B. salicis</i> (Day 1924) Chester 1939	Bacterial wilt, water mark	Vascular wilt	<i>Salix</i> species
Status quo <i>Erwinia</i> group			
<i>E. amylovora</i> (Burrill, 1882) Winslow et al., 1920	Fire blight	Necrogenic	Members of the Rosaceae
<i>E. billingia</i> Mergaert et al., 1999	Associated with cankers	Secondary invader	Members of the Rosaceae
<i>E. cypripedii</i> (Hori) Bergey et al., 1923	Brown rot	Maceration	<i>Cypripedium</i> and other orchids
<i>E. mallotivora</i> Goto, 1976	Black leaf spot	Necrogenic	<i>Mallotus japonicus</i> tree
<i>E. persicinus</i>	Red-brown fruit rot	Necrogenic	Cucumber, tomato, banana
<i>E. psidii</i>	Fruit rot	Necrogenic	Guava
<i>E. pyrifoliae</i> Kim et al., 1999	Leaf and stem blight	Necrogenic	Pear, <i>Pyrus pyrifolia</i> cv Shingo
<i>E. rhapontici</i> (Millard) Burkholder 1948	Crown rot	Maceration	Rhubarb
<i>E. tracheiphila</i> (Smith, 1895) Bergey et al., 1923	Cucumber wilt	Vascular wilt	<i>Cucumis</i> species
<i>P. carotovora</i> subsp. <i>Carotovora</i> (Jones) Bergey et al., 1923	Storage soft rot	Maceration	Harvested corms, tubers, roots, bulbs
<i>P. carotovora</i> subsp. <i>Chrysanthemi</i> Burkholder et al., 1953	Stem blight, wilt	Vascular wilt	Corn, carnation, chrysanthemum, tropic plants, e.g., <i>Philodendron</i> , <i>Dieffenbachia</i>
<i>P. carotovora</i> subsp. <i>atroseptica</i> (van Hall 1902) Dye 1969	Blackleg	Vascular wilt	Potato roots, lower stems, tubers
<i>P. carotovora</i> subsp. <i>betavascularum</i>	Soft rot	Maceration	Beet, <i>Beta vulgaris</i>
<i>P. carotovora</i> subsp. <i>odoriferum</i>	Soft rot	Maceration	Endive and chicory
<i>P. carotovora</i> subsp. <i>wasabiae</i>	Soft rot of excised petioles	Maceration	Japanese green horse radish
Erwinia species emended to Enterobacter species			
<i>Enterobacter cloacae</i>	Internal yellowing, brown-black discoloration	Diffuse necrogenic	Papaya (<i>Carica papaya</i> L.) Onion (<i>Allium cepa</i> L.)
<i>En. nimipressuralis</i>	Wet wood	Necrogenic	Elm
<i>En. cancerogenus</i>	Canker	Necrogenic	Poplar
<i>En. dissolvens</i>	Rot	Slow maceration	Corn

Soft-rotting group proposed emendation from *Erwinia* to *Pectobacterium* (Hauben et al., 1998).

Isolation

Erwinia species and species of its subspecific genera can be isolated from diseased tissues most expeditiously from fresh samples. Most *Erwiniae* are not fastidious with regard to the medium used, but it has been a general practice to employ relatively rich media such as Luria-Bertani (LB) agar, which contains per liter 10g tryptone (Difco), 5g yeast extract, 5g sodium chloride, 15g agar; and medium 523, which contains per liter 10g sucrose, 8g tryptone, 4g yeast extract, 2g dipotassium phosphate, 0.3g magnesium sulfate, and 15g agar. Supplements, such as 1% sorbitol, are added to LB agar medium for *E. amylovora* and related species. Although LB has been the most popular agar medium for isolation, nutrient agar (NA), which contains per liter 3g beef extract, 5g peptone, 8g sodium chloride and 15g agar, also has been used. Since NA was designed as general purpose medium for the isolation of mammalian bacterial pathogens, its use is not recommended for *Erwinia* and its subgeneric species that are associated with plants. For example, *Pantoea* species grow poorly on this medium. Some laboratories routinely have used NA supplemented with glycerol to compensate for poor growth of *Erwinia* species. This is poor practice. *Pantoea* species generally will grow more profusely when the medium is supplemented with nicotinic acid. For *Erwinia* species that produce excessive acid, medium YGC is used. Medium YGC agar contains per liter 20g glucose, 10g yeast extract, 20g ultrafine calcium carbonate and 15g agar. A clear zone surrounding each colony results from acid secretion, which liberates the carbonate as CO₂. The usual temperature for culture of *Erwinia* and its generic members is 28°C. An incubator with anti-desiccation features such as a humidifier (e.g., Kendro HeraCell) is preferable. Agar plates are incubated in the inverted position.

Identification

Erwinia and its subgeneric members usually are motile rods bearing peritrichous flagella and are able to ferment glucose leading to the formation of acid. Their fermentative pathway yields mixed acids and 2,3-butanediol. They are unable to utilize starch as a carbon source except for *E. rhapontici*, which produces a weakly diffusible pink pigment called ferrerosamine (Feistner et al., 1983). *E. rubrifaciens* (*B. rubrifaciens*) produces a water soluble, diffusible red pigment called rubrifacine A (Fistner et al., 1984) on yeast-glucose calcium carbonate agar. Some strains of *Pectobacterium chrysanthemi* produce yellow colonies streaked with a green-blue pig-

ment. All are catalase positive and negative for exocellular cytochrome oxidase activity. Except for the *Erwinia* species that cause soft rot, the necrogenic and vascular wilting group reduce nitrate. On LB or 523 media, their colonies are generally mucoid and domed and can vary in color from white to cream.

Members of the genus *Pantoea* produce colonies that may appear either as yellow to taupe or mauve on LB agar. In contrast to the *Erwinia* group, *Pantoea* species oxidize glucose to gluconate. The genus *Pantoea* includes phytopathogens *P. stewartii*, *P. ananas*, *P. citrea* and *P. agglomerans* pv. *milletiae*, *P. agglomerans* pv. *gypsophilae*, and *P. agglomerans* pv. *betae*. *P. ananas* (*P. ananatis*) causes brown patches on internal portions of pineapple fruit [*Ananas comosus* (L.) Merr.] and honeydew melon (*Cucumis melo* L.). The disease in pineapple is called "marbling." *P. uredovora* first was described as an epiphyte on uredospores of *Ustilago* smut of maize and on the panicles of barley, buckwheat and rice. Based on recent 16S rDNA sequence data, *P. ananas* and *P. uredovora* are homologous and, therefore, the specific name *P. ananas* takes precedence with *P. uredovora* as a retired species name. *P. ananas*, changed to *P. ananatis* (Hauben et al., 1998) is a Gram-negative, rod-shaped, facultative anaerobe and usually forms yellow, semimucoid colonies on YGC agar. Some strains contain the ice nucleation gene *inaA*, somewhat similar to *inaW* and *inaZ* genes of *Pseudomonas syringae* and *P. fluorescens*. *Pantoea citrea* causes pink disease of pineapple (Cha et al., 1998). *P. citrea* is Gram-negative, rod-shaped, facultative anaerobe, and produces pili. It causes the hypersensitivity response in tobacco and, therefore, contains *hrp* genes. On nutrient agar and trypticase soy agar, the colonies are entire, smooth, glistening, translucent, but not mucoid. As the colonies age, they turn taupe with a slight depression in the center. *P. citrea* produces two quinoprotein glucose dehydrogenases encoded by *gdhA* and *gdhB* genes (Pujol and Kado, 1999). The glucose dehydrogenase encoded by *gdhB* efficiently converts glucose into gluconate, which, in turn, is oxidized to 2-keto-gluconate. This latter substrate is further oxidized into 2,5-diketogluconate, a highly unstable compound that is chromogenic. *P. punctata* and *P. terrea* can oxidize glucose via the *gdhA* pathway. *P. citrea* harbors a cryptic plasmid with 5,229 base pairs. The plasmid, designated pUCD5000, is required for the full expression of the pink disease (Pujol and Kado, 1998).

P. stewartii subsp. *stewartii* causes Stewart's bacterial wilt and leaf blight disease of corn. This bacterium produces copious amounts of exopolysaccharides, the profuseness of which is believed to cause plugging of vessel elements in the host plant. Beginning symptoms are water-

soaked lesions, followed by vascular wilting on seedlings and leaf blight of mature plants. Some strains that cause leaf spots on foxtail millet (*Setaria italica*) and pearl millet (*Pennisetum americanum*) have been placed in *P. stewartii* subsp. *indologenes* (Mergaert et al., 1993). Multiple numbers of cryptic plasmids are core-sidents in *P. stewartii* subsp. *stewartii*. The replication and mobilization loci in cryptic plasmids pSW100 and pSW200 from *P. stewartii* subsp. *stewartii* share sequence homologies with pUCD5000 from *P. citrea*. The habitats of members of the genus *Pantoea* are listed in Table 2. The physiological and biochemical characteristics of *Erwinia* and its related genera are shown in Table 3.

Cultivation

P. citrea may be cultured on MGY medium (10g mannitol, 2g of sodium L-glutamate, 0.5g of monobasic potassium phosphate, 0.2g of sodium chloride, 0.2g of magnesium sulfate, 0.25g yeast extract per liter, adjusted to pH 7.0 with 3 N NaOH) at 30°C. The rusty red color produced by *P. citrea* may be generated in canned pineapple juice. The juice is clarified by centrifugation (12,000 × g, 10 min, 4°C) and adjusted to pH 6.0 with 3 N NaOH. The clarified juice is sterilized by filtration (0.4 μm-pore-size polycarbonate membrane filter; Phoretics Corporation, Livermore, California).

Table 2. Habitat and disease produced by members of the *Pantoea* group.

Species	Disease name	Disease type	Natural host
<i>P. agglomerans</i> pv. <i>agglomerans</i>	Stem darkening	Secondary	Celery
<i>P. agglomerans</i> pv. <i>betae</i>	Root gall	Tumorigenesis	Table beets <i>Beta vulgaris</i> L.
<i>P. agglomerans</i> pv. <i>gypsophilae</i>	Bacterial gall	Tumorigenesis by indole-3-acetic acid production	Baby's breath <i>Gypsophila paniculata</i> L.
<i>P. agglomerans</i> pv. <i>milliteae</i>	Bacterial gall	Tumorigenesis	Japanese wisteria <i>Wisteria floribunda</i>
<i>P. ananatis</i>	Marbling	Soft rot	Pineapple, sugarcane, honey dew melon
<i>P. citrea</i>	Pink disease	Translucent rot	Pineapple, mandarin orange
<i>P. dispersa</i>	Saprophyte	None	Edaphosphere resident, seeds
<i>P. punctata</i>	Brown spot	Delayed maceration	Mandarin orange
<i>P. stewartii</i> subsp. <i>indologenes</i>	Brown spot	Necrogenic	Graminae
<i>P. stewartii</i> subsp. <i>stewartii</i>	Stewart's wilt	Vascular wilt	Corn
<i>P. terrea</i>	Saprophyte	None	Soil inhabitant

Table 3. Comparative physiological and biochemical characteristics of *Pantoea* spp. versus *Erwinia* spp.

Characteristic	<i>Erwinia</i> spp.	<i>Pantoea</i> spp.	<i>Pectobacterium</i> spp.	<i>Brenneria</i> spp.	<i>Enterobacter</i> spp.
Gram-negative rods	+	+	+	+	+
Motile by peritrichous flagella	+	+/-	+	+	+
Facultative anaerobe	+	+	+	+	+
Colonies yellow or mauve	-	+	-	-	-
Percent genomic G+C content	49.8-54.1	55.1-60.6	50.5-56.1	50.1-56.1	52.0-54.0
Gluconate dehydrogenase	-	+	-	-	-
Cytochrome oxidase released	-	-	-	-	-
Catalase released	+	+	+	+	+
Indole production	-	+/-	-/+	-	-
Nitrate reduced to nitrite	+	+/-	+	-	+
H ₂ S produced from cysteine	+/-	-	+	+	-
Urease produced	-	-	-	-/+	-
Gas produced from glucose	-	-	+	-	+
Ornithine decarboxylase	-	-	-	-	+
Lipase	-	+	-	-	-
Acid from α-methylglucoside	+	-	-	-/+	-
Gelatin liquefaction	-/+	-	+	-	+
Acid from sorbitol	+	-	+	+	+
L-Malate utilized	+	+	+	+	+
DNase produced	-	+/-	-	-	-

Symbols: the +/- symbol indicates that a majority of species are positive; -/+ symbol indicates that a majority of species are negative.

Preservation

Erwinia and its related genera can be stored indefinitely in the lyophilized state. Cells in exponential phase of growth are harvested by centrifugation and resuspended in 1% sterile solution of powdered milk (Carnation brand). An appropriate aliquot of the mixture is placed in an ampoule and is quickly frozen in liquid nitrogen or in ethanol containing chunks of solid CO₂. The frozen mixture is lyophilized under vacuum until it is completely desiccated. The ampoule is sealed in vacuo with a torch, appropriately labelled, and stored in a cold room at temperatures between 4 and 16°C. For routine use, it may be convenient to store cultures in the frozen state. In this case, bacterial cells are resuspended in 1% sterile solution of powdered milk prepared in 10% glycerol. The mixture is stored at -70°C. Storing the mixture at -20°C is not recommended. Short-term (1 year maximum) storage of the isolate can rely on specialized media such as Preservation agar (P agar), which contains per liter 5g peptone, 5g sodium chloride, 0.03g cysteine, and 10g agar. The medium is autoclaved in completely filled screw capped tubes. Bacteria are preserved as stab cultures that were allowed to grow for about 4–8 days and then stored at 4°C.

Genetics

As members of the *Enterobacteriaceae*, *Erwinia*, *Enterobacter*, *Pantoea*, *Pectobacterium* and *Brenneria* are all amenable to genetic manipulation. The molecular genetic tools used in studies dealing with *Escherichia coli* are directly applicable to the study of members of this group of bacteria. Generally the plasmid replicons that contain the origin of DNA replication of the ColE1 plasmid of *E. coli* replicate well in these bacteria. Various nonreplicative plasmids, such as those containing the origin of DNA replication of plasmid R6K (which requires an accessory initiator protein like π for replication), have been used to deliver transposable elements to generate mutants. Essentially, the vector harboring the R6K origin is unable to replicate in the recipient bacteria, thus leaving behind the transposon that jumped onto the chromosome of the recipient. Transposon mutagenesis has opened the way to identify genes involved in various metabolic and physiological pathways in these bacteria. When the bacterium of interest is not amenable to transposon mutagenesis, chemical mutagenesis using nitrosamine and alkane sulfonic esters, such as nitrosoguanidine and ethyl methane sulfonate, respectively, have been used. Chemically derived mutants defective in the phenotype of interest

would be identified in the affected gene by genetic complementation using a genomic library of the parental strain. Besides the generation of mutants, chromosomal genes can be mobilized by a transducing phage if available. The transducing bacteriophage π M1 was used to transfer chromosomal markers in *Erwinia carotovora* subsp. *atroseptica* (Toth et al., 1997). Because of their economic importance, a number of genes involved in pathogenicity and virulence have been identified in *Erwinia* generic group members. The general approach has been to generate mutants affected in a given phenotype, followed by the isolation of the gene or genes responsible for the phenotype, and characterization of the product or products made by the gene or genes of interest. Hence, this approach has been used to identify the genes (avirulence genes) involved in eliciting the hypersensitivity response in non-host plants. The hypersensitive response-pathogenicity or *hrp* genes have been identified in several necrogenic strains of this group of bacteria.

Epidemiology

The disease cycle of this group of bacteria can be classified according to the way they infect and cause disease. For the necrogenic group of pathogens, there are good examples of insect transmission of the pathogen generally infecting at the early blossom stage of the host plant. For example, the fire blight pathogen *Erwinia amylovora* is transmitted primarily by the honeybee that becomes contaminated or infested by this bacterium during visits to blossoms and oozing sap of an infected tree. *Enterobacter cloacae*, the cause of the internal yellowing disease of papaya fruit, is transmitted by the oriental fruit fly (Nishijima et al., 1987). The dissemination of pink disease appears to be by fruit flies, since timely applications of insecticides dramatically reduces the incidence of this disease. Although transmission of necrogenic bacteria is vectored efficiently by insects, cultural practices also facilitate the spread of this group of bacteria. For example, the mechanical harvester transmits *Erwinia rubrifaciens* (emended as *Brenneria rubrifaciens*) from diseased walnut trees to healthy trees (Kado and Gardner, 1977). The disease cycle of this group of bacteria originates from diseased material in the form of ooze harboring the inoculum that is picked up either by flying insects or harvesting machinery and transmitted to various portals of entry on the host.

Bacteria of the macerative group, represented by members of the genus *Pectobacterium*, have a disease cycle usually associated with the rhizosphere. Infected plant parts tilled into the soil

serve as reservoirs for bacteria belonging to this group. For example, *Pectobacterium carotovora* subsp. *carotovora* is known to infect various tuber, corn, and bulbs of vegetable and ornamental crops. Replanting in soils containing the infected plant parts exposes the new seedlings, seed pieces, etc., to resident macerative bacteria like *P. carotovora* subsp. *carotovora*. Wounds caused by harvesting equipment allow entry of the organism into host tissues where infection is initiated. Microaerophilic and anaerobic conditions created by packing the harvested crop into bins or rail cars are most conducive for soft rot. The commercial processing of vegetables that usually are washed in large baths can become contaminated by the bath water used to wash a diseased tuber, root, etc. Dressing water often becomes contaminated with these bacteria and any resulting wounds made during the vegetable washing process are usually sites for postharvest infection that is usually seen at the produce processing station in supermarkets.

Members of the vascular wilt group infect their host plant systemically. It is thought that because organisms can multiply quickly and elaborate exopolysaccharide materials in the vascular system, they cause occlusion of the vessel elements culminating in dieback and wilting symptoms. The disease cycle of this group of pathogens, typified by *Pantoea stewartii* subsp. *stewartii*, includes the transmission of the bacterium by an insect vector. In the case of *P. stewartii* subsp. *stewartii*, the corn flea beetle (*Chaetocnema publicaria*) disseminates the pathogenic bacterium in cornfields. *Erwinia tracheiphila*, which causes bacterial wilt of cucumber and related bacteria, is spread via the striped cucumber beetle (*Acalymma vittata*) and the spotted cucumber beetle (*Diabrotica undecimpunctata*). Interestingly, these bacteria overwinter in the insect.

The tumorigenic group is best represented by *Pantoea agglomerans* pv. *gypsophilae*, which induces tumors or galls on *Gypsophilum* (Baby's Breath). The source of inoculum is primarily from diseased plants bearing galls or nodules. Infected plant stocks, usually originating from a nursery that does not follow sanitation practices, spreads this organism.

Disease

Members of the genus *Erwinia*, *Enterobacter*, *Pantoea*, *Pectobacterium*, or *Brenneria* are associated with plants, and many are pathogens of specific plant species. For example, *Erwinia amylovora* favors plants of the Rosaceae family (apple, pears, quince), whereas *Pantoea stewartii* subsp. *stewartii* infects plants of the maize family

specifically *Zea mays* L. (sweet corn); and *Brenneria rubrifaciens* infects specifically walnut trees of the species *Juglans regia*, with *J. regia* cv. *Hartley* being the most susceptible commercial cultivated variety. Hence, pathogens of these five genera display host specificity, even though species of the genus *Pectobacterium* infect a relatively wide range of tuber-, corn- and bulb-crops.

Host specificity is conferred by specific residence-establishing genes, defined herein as "res" genes and is assisted by the products of the *hrp* genes (for hypersensitive response pathogenicity). *Res* genes play an important role in maintaining ecological fitness (either in the rhizosphere or phyllosphere) of the pathogen. The importance of *res* genes in conjunction with *hrp* (or *hrp*-equivalent genes) genes is exemplified in other bacterial systems such as with *Agrobacterium tumefaciens*, where an isoflavonoid-inducible efflux pump is essential for competitive colonization of roots (Palumbo et al., 1998); with *Pseudomonas syringae* pv. *syringae*, where certain *hrp* genes (*hrpJ* and *hrpC*) are needed for epiphytic growth (Hirano et al., 1999; Yu et al., 1999); and with *Xanthomonas campestris* pv. *campestris*, where the *hrpXc* regulatory gene was found essential for colonizing cauliflower plants (Kamoun and Kado, 1990) and is highly conserved among all *Xanthomonas* pathovars (Oku et al., 1998).

The combined activities of the *res* gene and *hrp* genes, which are involved in the secretion and injection of pathogenicity factors via a Type III secretion system into the cells of the host plant, are essential for establishing epiphytic fitness. The functional role of the *res* and *hrp* genes are not mutually exclusive because the effectors, which are encoded by the *res* and *hrp* genes, require the Type III secretion system, which is also encoded by *hrp* genes and injected into the host cell by the bacterial pathogen. The Type III secretion system is encoded by a cluster of genes contained within a pathogenicity island. More than one Type III secretion system may exist in a pathogen, with each being encoded by separate pathogenicity islands. For example, two distinct virulence-associated Type III secretion systems are encoded within pathogenicity islands, SPI1 and SPI2, of *Salmonella* spp. (Hensel et al., 1997; Galán and Collmer, 1999). The Type III secretory pathway involves approximately 20 proteins that carry exoproteins directly from the cytoplasm to the cell surface, from where they are then injected into an animal or plant cell upon contact (depending whether the member of the *Enterobacteriaceae* is a mammalian or plant pathogen).

The Type III secretion system and the effector proteins are highly conserved and are related to those in other members of the *Enterobacteriaceae* such as *Yersinia*, *Salmonella*, and *Shigella*

(Galán and Collmer, 1999). The conservation of the Type III secretion apparatus and most of the effector proteins reflect the conservation of the genes of the pathogenicity island that was likely acquired by horizontal gene transfer. This is supported by the presence of homologs of genes in the *hrp* pathogenicity island in *Erwinia amylovora* to those in *Ralstonia solanacearum*, *Xanthomonas campestris* pv. *campestris*, *Pseudomonas syringae* pv. *syringae*, *Yersinia enterocolitica*, *Shigella flexneri*, and *Salmonella typhimurium* (Bogdanove et al., 1996). Thus, Type III secretion systems are functionally conserved as well. For example, the Type III secretion system of *X. campestris* pv. *vesicatoria* is able to secrete PopA of the Hrp system in *Ralstonia solanacearum*; AvirB of *Pseudomonas syringae* pv. *glycinea*, and the cytotoxin YopE of *Yersinia pseudotuberculosis* (Rossier et al., 1999).

The overall role of the Type III secretion system is to deliver virulence and pathogenicity effectors that establish and maintain infection and cause disease. Loss of this delivery system's function results in an avirulent phenotype and the inability to compete effectively in the infection court, defined here as the site of infection whether it be on the roots or foliage of the plant. Pathogenicity of the *Erwinia* group of pathogens, therefore, is highly dependent on the Type III secretion system. Because the genes of the Type III system are highly conserved, these pathogens are likely to have originated through gene acquisition via a horizontal gene transfer system.

The Genera *Photorhabdus* and *Xenorhabdus*

NOEL BOEMARE AND RAYMOND AKHURST

Introduction

The genera *Photorhabdus* and *Xenorhabdus* are members of the family Enterobacteriaceae that encompass the intestinal bacterial symbionts living in commensalism with entomopathogenic nematodes (EPNs) of the genera *Heterorhabditis* and *Steinernema*, respectively (Akhurst and Boemare, 1990; Forst et al., 1997). Most of them are pathogenic for insects when injected into the hemocoel. In addition, some nonsymbiotic strains of *Photorhabdus* have been identified as opportunistic pathogens for humans (Farmer et al., 1989; Peel et al., 1999). Various insect and vertebrate symbionts are members of the γ -subclass of Proteobacteria, which contains a wide spectrum of animal and human pathogens, such as members of the families Enterobacteriaceae, Legionellaceae, Pasteurellaceae, Vibrionaceae, and the genera *Pseudomonas* (sensu stricto) and *Acinetobacter* (Stackebrandt, 1999). Symbionts of EPNs are phylogenetic neighbors of an important group of endosymbionts of insects (the RDP tree of the {Bergey's Web site}). Most of the insect endosymbionts cluster according to the phylogeny of their eukaryotic hosts, which may indicate coevolutionary events (Stackebrandt, 1999). A similar cospeciation (See Habitat/Cospeciation in this Chapter) also was observed in the case of EPNs (Akhurst, 1983; Boemare et al., 1997a; Forst et al., 1997).

However, though most of the insect symbionts are endocytobionts and not cultivable, *Xenorhabdus* and *Photorhabdus* have the distinct advantage of cultivability on standard bacteriological media. Moreover, their hosts can be easily axenized. Consequently, pure cultures of axenic nematodes and bacteria are available for combination in gnotobiological experiments that demonstrate the viability and performance (both qualitative and quantitative) of the bacterial/helminthic symbioses (Boemare et al., 1997a). Other bacterial–animal symbioses involving cultivable Proteobacteriaceae have been described: some marine animal light-organ symbionts (Nealson et al., 1990) such as the model *Vibrio*

fischeri (associated with the squid *Euprymna scolopes*) and *Aeromonas veronii* bv. *sobria* (symbiont of the medicinal leech *Hirudo medicinalis*). In this latter, despite the diverse bacterial flora found along the tegument of the leech, the *A. veroni* bv. *sobria* are typically found as a pure culture in the gut, suggesting that these symbionts possess a special capability that enables them to proliferate in the medicinal leech (Graf, 2000). *Vibrio harveyi*, often commensal with marine animals, may be pathogenic for the black tiger prawn, *Penaeus monodon* (Manefield et al., 2000), as are the terrestrial luminous *Photorhabdus* for insects.

Taxonomy

Initially only one genus, *Xenorhabdus*, was described as encompassing all the symbionts of the entomopathogenic nematodes. Those strains initially considered as belonging to the species *Xenorhabdus luminescens* clearly form a DNA-relatedness group that is distinct from all the other *Xenorhabdus* strains (Akhurst et al., 1996; Boemare et al., 1993). These DNA data, together with the significant differences in phenotypic characters between “*X. luminescens*” and the other *Xenorhabdus* species (Akhurst and Boemare, 1988; Boemare and Akhurst, 1988), differences in fatty acid composition (Janse and Smits, 1990), and chemotaxonomic data (Suzuki et al., 1990) led to the transfer of *X. luminescens* into a new genus, *Photorhabdus*, as *Photorhabdus luminescens* comb. nov. (Boemare et al., 1993). Nevertheless, comparison of 16S rDNA sequences of the type strains of *Photorhabdus* and *Xenorhabdus* species indicate the close phylogenetic relationship of these two genera (Rainey et al., 1995). The Ribosomal Dataset Project (RDP) tree established that the two genera branch deeply in the family Enterobacteriaceae without any common ancestor. They are neighbors of *Proteus vulgaris* and *Arsenophonus nasoniae*, and between *Salmonella*, *Erwinia*, *Serratia*, and several endosymbionts of insects (*Hafnia*, *Rahnella* and *Yersinia*; Liu et al., 1997;

the RDP tree of the {Bergey's Web site}). All *Xenorhabdus* strains could be clearly distinguished from all strains of *Photorhabdus* by the 16S rDNA signature sequences; *Xenorhabdus* have a TTTCG sequence at positions 208–211 (*E. coli* numbering) of the 16S rDNA, whereas *Photorhabdus* have a TGAAAG sequence at positions 208–213 (Szállás et al., 1997).

There are also biological arguments to distinguish these two genera. In all the microbial ecological surveys undertaken in the five continents (more than 100 independent reports), a *Xenorhabdus* isolate has never been recovered from *Heterorhabditis* or a *Photorhabdus* from *Steinernema*. Moreover, by testing the specific interaction with the nematode host, gnotobiological experiments demonstrate that *Photorhabdus* isolates do not support culture of any *Steinernema* species in vitro (Akhurst, 1983), although in some combinations, they support culture of non-host *Heterorhabditis* spp. (Akhurst and Boemare, 1990; Han et al., 1990). Similarly *Xenorhabdus* spp. do not support culture of *Heterorhabditis* (Akhurst, 1983).

For identifying the diversity of the *Photorhabdus* and *Xenorhabdus*, a fast method using the polymorphism of the 16S rRNA genes was described by Brunel et al. (1997). Fischer-Le Saux et al. (1998) applied this polymerase chain reaction–restriction fragment length polymorphism (PCR-RFLP) method (Fig. 1), which gives an excellent estimation of the diversity of the genus by using efficient restriction endonucleases after first checking that they provide the most discriminative restriction patterns within the given sample. It allows analysis of a large sample of different isolates giving a series of genotypes, each one corresponding to a specific restriction pattern. Based on the total amplified sequence of the 16S ribosomal RNA genes, the method provides reference restriction patterns for identifying other isolates.

According to rule 65 (2) of the *International Code of Nomenclature of Bacteria*, generic and subgeneric names, which are modern compounds of two or more Latin or Greek words, have the gender of the Greek or Latin word used as the last component of the compound. Consequently, *Photorhabdus* and *Xenorhabdus* (genera with names ending in *rhabdus* [from *rhabdos*, the Greek word for rod] are feminine) become in modern Latin feminine words, explaining the feminine species and subspecies names when they refer to adjectives (Euzéby and Boemare, 2000). Thus, “*X. nematophilus*” and “*X. japonicus*” become *X. nematophila* and *X. japonica*, and the new species of *Photorhabdus*, *P. temperata* and *P. asymbiotica*. Otherwise when the species names refer to an author, they take the gender of the author, such as *X. bovienii*, *X.*

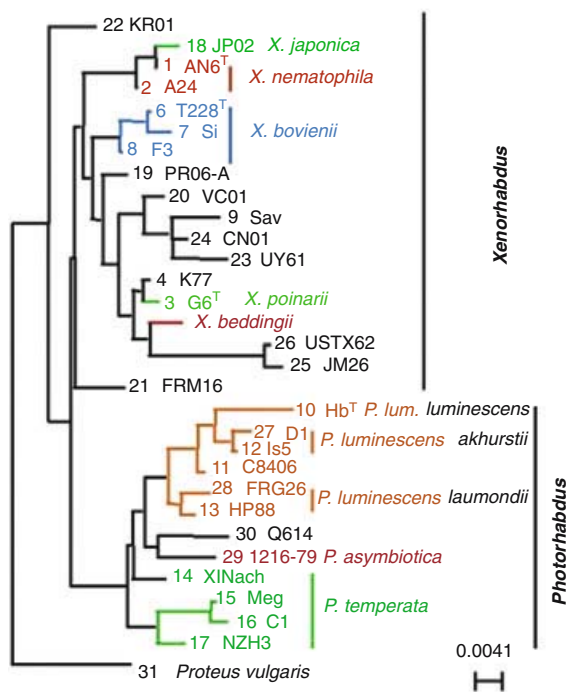

Fig. 1. Phylogenetic tree from PCR-RFLP 16S rDNA genotypes *Xenorhabdus* and *Photorhabdus*. The neighbor-joining method was applied to 30 defined genotypes, from a total of 117 strains. The number of the genotype according to Fischer-Le Saux et al. (1998) is followed by the name of the representative strain.

poinarii, *X. beddingii*, *P. luminescens* subsp. *laumondii* and *P. luminescens* subsp. *akhurstii*.

Habitat

Life Cycle

Symbionts of EPNs live in two different habitats during their life cycle: they survive in the gut of the free-living stage of their nematode host, and they are inoculated into and multiply in the body cavity of insects, thus creating a pure monoxenic culture (See Habitat and Ecology sections of the chapters *Photorhabdus* and *Xenorhabdus*). So the life cycle of the EPN symbionts is unique because it involves both symbiosis of nematodes and pathogenesis of insects, as summarized in Fig. 2. The infective juveniles (also named “dauer” larvae), which are the nematodes’ third stage, search (cruiser species) or wait (ambusher species; Gaugler, 1993) for an insect prey (step 1). When the target insect is found they penetrate by natural openings (mouth, anus, spiracles) or directly through the tegument (mainly *Heterorhabditis*). During penetration, the nematodes exsheath the second stage cuticle, which was retained during their period in the soil, before

Fig. 2. Life cycle of entomopathogenic nematodes and their bacterial symbionts.

entering into the body cavity of the insects (step 2). They transform into the fourth and adult stages and during this time induce a toxicogenesis (Boemare et al., 1983b; Boemare et al., 1982), releasing an immune depressive factor (step 3) active against antimicrobial peptides produced by the insects (Götz et al., 1981). This immune depressive factor is presumably a protease that facilitates release of the nematode's bacterial symbionts (step 4). The bacteria multiply, and at the final stage, the insects die due to the septicemia (step 5). Depending on the insect, nematode and bacterial symbionts, the pathogenic process can be the result of the action of one partner or both together (see *Xenorhabdus*/Ecology in this Chapter). Sometimes a toxemia induced by the symbiont precedes the resulting septicemia (Forst et al., 1997). At the end of the bacterial multiplication, production of a large variety of antimicrobial compounds (see *Photorhabdus* and *Xenorhabdus* in this Chapter) prevents microbial contamination, mainly from the insect intestinal microflora. By using the food supplies provided by the bacterial biomass and the metabolized insect tissues (step 6), the nematodes reproduce in the insect cadaver (step 7) for one, two or three generations. Thus, bacteria create suitable conditions for the development of their nematode host in the insect cadaver. At the end of the parasitism, the recruitment of some bacterial cells by the dauer larvae of the nematodes (step 9), before leaving the insect (step 10), maintains the perenniality of the symbiosis through the generations.

Physiology

Phase Variation

A highly significant feature of bacteria of the genera *Photorhabdus* and *Xenorhabdus* is a

phase variation that occurs during the stationary period of the growth cycle (Akhurst, 1980). It can be easily detected by two major properties: dye adsorption and antibiotic production. Only phase I of the symbionts has been detected in nature, but under in vitro conditions, a variable proportion undergoes profound change affecting colony and cell morphologies, motility, secondary metabolites, endo- and exo-enzymes (including respiratory enzymes; Akhurst, 1980; Boemare and Akhurst, 1988; Givaudan et al., 1995; Smigielski et al., 1994b). The timing and extent of the phase change is largely unpredictable, but the rate of change from phase I to phase II is generally greater than the reverse. In contrast to *Photorhabdus* where no reversion has yet been reported, the revertants obtained with *X. nematophila* (Akhurst and Boemare, 1990; Givaudan et al., 1995) indicate that the variation in the genus *Xenorhabdus* better fits the classical definition of phase variation. Indeed, phase variation in bacteriology is commonly accepted as a reversible genetic event usually mediated by DNA instability such as DNA inversion. Usually such a phenomenon affects one or a small number of gene products and is reversible at a significant frequency. In the case of *Photorhabdus*, many phenotypic traits are altered in phase II variants and no reversion has been confirmed. Some described "revertants" came from intermediate variants (Krasomil-Osterfeld, 1995), but not from true phase II variants, which have a complete loss of phase I phenotypic traits. Consequently the use of the phrase "phase variation" for *Photorhabdus* phenotypic shifts is not exactly appropriate, but is commonly used to refer to an alternative balance in expression/nonexpression of physiological traits from the same genome.

In general, variation in phase-related characters of *Photorhabdus* and *Xenorhabdus* has been

Table 1. Phase characters of *Photorhabdus* and *Xenorhabdus*.

reported qualitatively (“+” and “–”). However, for every character that can be quantified (e.g., luminescence and antibiotic production), it is clear that the difference between phases is a matter of magnitude, not presence or absence. It is highly probable that this holds true for all phase-related characters.

Table 1 summarizes the characters affected by phase variation. The bacterium isolated from the infective stage (dauer larvae) was named the phase I variant (Boemare and Akhurst, 1988). Phase I colonies are mucoid and stick to the loop when streaked on plates, produce antibiotic molecules (Akhurst, 1982a), adsorb dyes when incorporated into agar (e.g., the neutral red in MacConkey agar). Phase II appears spontaneously during stationary growth period from in vitro culture and during nematode rearing on artificial diets. Phase II colonies are not mucoid, do not adsorb dye and do not produce antibiotics.

Numerical analyses of phenotypic data for the two phase variants of multiple *Xenorhabdus* and *Photorhabdus* strains correspond to the genotypic definition of species (Fig. 3). However, these analyses also show that phase variation is a general phenomenon throughout the genera that results in conspecific strains grouping by phase status before grouping by species (compare Fig. 3a with Fig. 3b, where some phase-related characters are deleted from the analysis). Phase variation is a general phenomenon at the infra-specific level for both genera. It does not affect the phenotypic clustering of the species, although phase variants are more similar inside

each species. However, depending on the phase characters affected for each strain, clustering by phase variants or by strains may be different. Thus, some strains have phase variants differentiated by many characters (e.g., strains F1 and A24 of *X. nematophila*, strains Q614 and HI of *Photorhabdus*; Fig. 3b), others have only a few characters distinguishing the two phase variants (strains SK2 of *X. bovienii* and NC116 of *X. nematophila*; Fig. 3a).

The variation between phases in phenotypic data has been the source of some discrepancies between results published by different laboratories. Consequently, before starting the analysis of such phenotypic characters, we have to recommend an accurate screening of clones. Thus, for a taxonomic study, the two extreme clones of each strain expressing the largest number of different phenotypic responses to bacteriological tests, designated as phase I and phase II variants, must be selected. Clones that are intermediate (i.e., expressing some phase I and some phase II characters) should be eliminated from a taxonomic study, particularly for the genus *Photorhabdus*. Practically, before any mathematical treatment devoted to the taxonomy of species, the physiological data is compiled to check any positive response of related clones to a strain, and to be consistent with the definition of all the potentialities of the given strain. This is also a reason to take great care to harvest isolates expressing all the strain properties during the isolation from the nematode host. Conversely, these intermediate expressions are of great interest for genetic studies.

Fig. 3. Numerical analysis of phenotypic data from *Xenorhabdus* and *Photorhabdus* phase variants. All the data are treated as two-state (0,1) characters. Characters that were positive or negative for all isolates (i.e., that were not discriminative) were deleted (180/240). Similarity coefficients were calculated with the Jaccard coefficient (Sneath and Sokal, 1973). To construct dendrograms, the internode lengths were calculated for each coefficient by complete linkage clustering (furthest-neighbor sorting strategy: FNS) using the GENSTAT program (Alvey et al., 1980). However, simple linkage (nearest-neighbor clustering), group-average sorting (UPGMA), weighted clustering (WPGMA), unweighted and weighted centroid clusterings were also tested (not shown) and gave comparable results. The dendrograms obtained with FNS best illustrated the universality of the phase variation concept occurring in both genera. Codification of isolates: N/1 = phase I variant of strain N; N/2 = phase II variant of strain N. (a) Dendrogram obtained with the 60 characters that were not common to both phases of all strains. Note that for no strain, except *X. bovienii* strain SK2 and *X. nematophila* strain NC116 where phase characters are poorly expressed, did the two phase variants cluster together before clustering with another strain. (b) Dendrogram obtained from the same data set with 55 characters, the 60 previous characters minus 5 identified as being the principal phase-related characters. They were: antibiosis, dye-binding, phospholipase, protoplasmic inclusions, pigmentation. When these phase-related characters were deleted from the analysis, both phase variants of each strain clustered together before clustering with another strain (except in *Photorhabdus* spp. and *X. nematophila*, groups where some strains expressed additional phase-related characters). Updated from data published by Akhurst and Boemare (1988).

Phase I variants provide and protect essential nutrients for the nematodes by killing and metabolizing the insect host and producing a range of antimicrobial agents. Although phase II variants may also kill the insect host and are

capable of colonizing the dauer vesicle of *Steinernema* or the anterior part of the intestine of *Heterorhabditis*, they are less effective in providing growth conditions for the nematodes (Akhurst, 1980; Akhurst, 1982a; Akhurst and

Boemare, 1990) and have never been found associated with naturally occurring nematodes. In addition some *Photorhabdus* phase II variants may be deleterious to their original *Heterorhabditis* (Ehlers et al., 1990).

Convergence

Photorhabdus-Heterorhabditis and *Xenorhabdus-Steinernema* symbioses are widely divergent. These symbioses are believed to use different mechanisms to maintain superficially similar associations. The similarities in their patterns of infectivity, life cycle and mutualism with nematode should be considered to result from evolutionary convergence. Indeed the symbiotic, pathogenic, and phase variation properties, which are the conditions for such associations (Boemare et al., 1997a), do not necessarily imply the same physiological mechanisms. Information gained from current genetic studies will probably clarify the picture of and help explain the convergent evolution of *Photorhabdus-Heterorhabditis* and *Xenorhabdus-Steinernema* symbioses (Boemare and Akhurst, 1994).

Applications

These bacteria are now recognized as potentially having great importance beyond their associations with nematodes (See Applications sections of *Photorhabdus* and *Xenorhabdus*). Recently, the use of *Photorhabdus* and *Xenorhabdus* genes encoding for entomotoxins to create transgenic plants for crop protection was proposed (Ffrench-Constant and Bowen, 1999). The particular properties of these bacteria in fundamental research terms (such as cellular exportation, exoenzymatic activities, production of many special metabolites, pathogenic processes, ability to differentiate into multicellular populations and colonize different micro-niches) were inducements for the Pasteur Institute and INRA (France) to sequence the whole genome of *Photorhabdus*, which will soon be available to the international community (Kunst et al., 2000; the http://www.pasteur.fr/recherche/unites/gmp/Gmp_projects.html#pl [Pasteur Web]). We believe that these two bacterial genera will provide in the coming years new insights for microbiology in terms of genetics and physiology, particularly on pathogenic mechanisms and specific metabolic pathways of prokaryote-eukaryote interaction. Presumably researchers also will be able to address shortly an evolutionary history for these mechanisms.

Genus *Photorhabdus*

Phylogeny

Only 16S rRNA gene sequence data are available for analyzing the phylogeny of *Photorhabdus*. However, these provide solid trees regardless of the clustering method used (neighbor joining, parsimony or maximum likelihood) for understanding the position of the genus in the radiation of the Enterobacteriaceae. Thus, 16S rDNA sequences from representative strains of *Photorhabdus* (Fischer-Le Saux et al., 1999b; Szállás et al., 1997) were compared to homologous sequences of several species of Enterobacteriaceae. Binary similarity values determined for *Photorhabdus* ranged above 96%, whereas the similarity values for *Photorhabdus* compared to *Xenorhabdus* and other Enterobacteriaceae strains were between 94–96% and 92–95%, respectively. PCR-RFLP analysis (Fischer-Le Saux et al., 1998) and sequence analysis (Fischer-Le Saux et al., 1999b; Szállás et al., 1997; Fig. 4) also verified the existence of three major 16S rRNA clusters that corresponded to the DNA-DNA relatedness groups (see Taxonomy in this Chapter). Depending on the out-group inserted and on dispersion of other related bacteria (Stackebrandt et al., 1997; Stackebrandt and Goebel, 1994), the *P. luminescens* subsp. *luminescens* may aggregate differently with other subgroups or even with *P. asymbiotica*. Nevertheless, sequence analyses of 16S rDNA show that all *Photorhabdus* strains branch deeply within the radiation of the family Enterobacteriaceae, and have a specific TGAAAG sequence at positions 208–213 (*E. coli* numbering). The nearest phylogenetic neighbor as demonstrated by PCR-RFLP (Brunel et al., 1997) and sequencing of 16S rRNA (Fischer-Le Saux et al., 1999b; Rainey et al., 1995; Suzuki et al., 1996; Szállás et al., 1997) is *Xenorhabdus*, then *Proteus*.

It appears that the genus *Photorhabdus* evolved after the main radiation of *Xenorhabdus* species occurred (Forst et al., 1997). This hypothesis, originally derived from the analysis of only seven strains (Rainey et al., 1995), was verified when the 16S rDNA analysis was extended to a balanced number of datasets from *Photorhabdus* and *Xenorhabdus* in comparison to other genera and families (Fischer-Le Saux et al., 1999b; Suzuki et al., 1996; Szállás et al., 1997).

Taxonomy

NOMENCLATURE AND FAMILY LINKING Poinar et al. (1977) isolated a bacterium from a previously unknown nematode, *Heterorhabditis* bacteriophora (Poinar, 1976), which was apparently similar to a *Xenorhabdus* sp. but noticeably

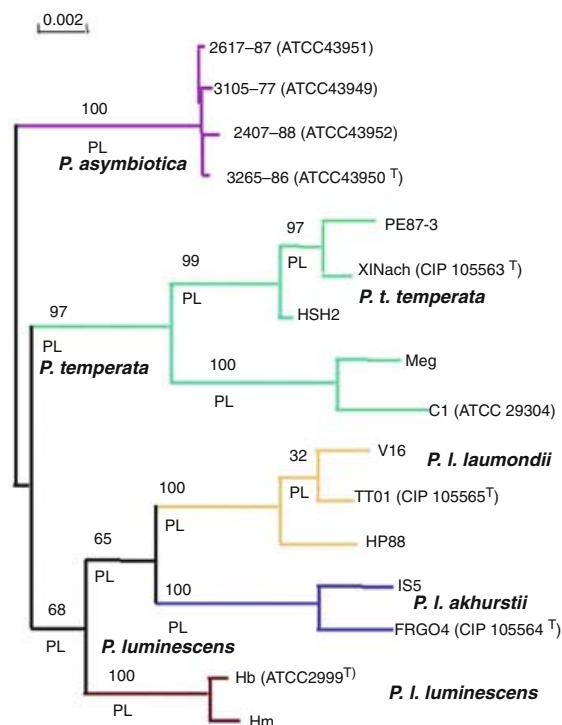

Fig. 4. Phylogenetic tree of *Photorhabdus* spp. from 16S rDNA sequences obtained by the neighbor-joining method (Saitou and Nei, 1987) using a bootstrap approach (Felsenstein, 1985) to determine the reliability of the topology obtained (numbers given above the nodes). Those clusters also obtained by parsimony (Kluge and Farris, 1969) and by maximum likelihood (Felsenstein, 1981) are indicated by a "P" and an "L" below the nodes, respectively. The accession numbers are given after the strain names. Internode values are only weak at the linkage of both subspecies *laumondii* and *akhurstii* with *luminescens*. Here no out-group has been inserted in the analysis to establish the diversity inside the group of *Photorhabdus*. Depending on the out-group inserted and on dispersion of other related bacteria (Stackebrandt et al., 1997; Stackebrandt and Goebel, 1994), the *P. luminescens* subsp. *luminescens* may aggregate differently with other subgroups or even with *P. asymbiotica*. Such proximity can be also observed by phenotypic analysis (see Fig. 6). The bar indicates a distance of 0.002 substitutions per site (s/s). (Modified from Fischer-Le Saux et al., 1999b).

luminous. They proposed inclusion of this luminous species in the genus as *X. luminescens* (Thomas and Poinar, 1979). However, the genus *Photorhabdus* was created in 1993 to accommodate this species as *Photorhabdus luminescens* comb. nov. (Boemare et al., 1993). Thus, due to the rules of bacterial nomenclature, the type species was named *Photorhabdus luminescens*, creating an unavoidable pleonasm.

By DNA/DNA hybridization, *Photorhabdus* is only 4% related to *Escherichia coli*, the type species of the type genus for the family. However, *Photorhabdus* possesses the enterobacterial common antigen (Ramia et al., 1982). These data

indicate that, although most biochemical tests used to differentiate the Enterobacteriaceae are negative for *Photorhabdus* and although this genus is only distantly related to the core genera of this family (Farmer, 1984), *Photorhabdus* should be retained in the Enterobacteriaceae. At present time the genus includes three species with four subspecies (Boemare and Akhurst, 2000; Fischer-Le Saux et al., 1999b).

THE POLYPHASIC APPROACH TO SPECIES DELINEATION Bacteriologists cannot delineate species by crossbreeding, a method used by other biologists, but rather by comparing the total DNA of strains hypothesized to be closely related. Indeed, DNA-DNA hybridization is the key method to delineate bacterial species inside a well-distinguished group (Wayne et al., 1987). Consequently a species in bacteriology is an artificial concept. It is defined as a group of strains sharing approximately 70% or greater DNA/DNA relatedness associated with 5°C or less change in melting temperature (δT_m). However, bacterial taxonomists recognize that these values are indicative rather than absolute (Vandamme et al., 1996). Based on data obtained using the S1 nuclease method, Grimont (1980) made the definition more robust by stating that strains having 80% reassociation with δT_m below 5°C did belong and those having less than 60% reassociation with δT_m more than 7°C did not belong to the same species. For reassociation values between 60 and 80%, or δT_m values between 5 and 7°C, strains should be carefully studied to delineate species.

Thus, by using the hydroxyapatite (HA) method to analyze DNA-DNA *Photorhabdus* heteroduplexes, two DNA-relatedness groups associated with nematode *Heterorhabditis* and one containing strains found in human clinical specimens (Farmer et al., 1989) were recognized (Akhurst et al., 1996). Recently, restriction patterns obtained after amplification of the 16S rDNAs allowed identification of 12 genotypes among *Photorhabdus* strains (Fischer-Le Saux et al., 1998). By hybridizing the DNA of some representative strains of each ribosomal genotype, and by using the S1 nuclease method, the previous three genomic groups were confirmed (Fischer-Le Saux et al., 1999b; Fig. 5). They exhibited between them DNA-DNA hybridization values lower than 42% with δT_m higher than 8.7°C. As reported before (Grimont et al., 1980), DNA reassociation values obtained with the S1 method were lower than those obtained with the HA method. Moreover, the phylogenetic trees inferred from the complete 16S rDNA sequence analysis (using neighbor joining, parsimony and maximum likelihood) delineate the same clusters as both DNA-DNA hybridization

Fig. 5. Interpretation of the DNA/DNA binding ratio data showing the levels of relatedness of *Photorhabdus* strains. Three clusters of DNA-reassociation values were delineated: (i) higher than 80% associated with δT_m lower than 1.5°C correspond to relatedness values between members of the same subspecies (dark pink boxes); (ii) 50–70 % with δT_m 4.5–7°C correspond to levels of relatedness occurring among members of different subspecies within a species (pink boxes); and (iii) lower than 40% with δT_m higher than 9°C correspond to reassociation values between members of different species (mauve boxes). The 16S rRNA genotype designations according to Fischer-Le Saux et al. (1998) are indicated between brackets after the strain names. (Modified from Fischer-Le Saux et al., 1999b.)

methods (Fig. 4). All members of these genomic groups clustered with high bootstrap confidence values.

Clustering of phenotypic data by multivariate correspondence analysis (Fig. 6) shows a good correlation with the previous genomic analyses (Figs. 4 and 5) and helped the taxonomist to recognize discriminative characters between the species. We note for instance (Table 2) that the maximum growth temperature, DNase, urease and indole production, utilization of mannitol and of DL-lactate, and esculin hydrolysis may be specific diagnostic characteristics depending on the species.

Symbols: +, 90–100% of strains are positive; [+], 76–89% are positive; d, 26–75% are positive; [+], 11–25% are positive; =, 0–10% are positive, w (e.g., [+]w), indicates a weak reaction.

Abbreviations of type strains: ATCC, American Type Culture Collection (Rockville, Md.); CIP, Collection de l'Institut Pasteur (Paris, France); ^T, type strain. ^aAll tests were done at 28°C ± 1°C unless otherwise noted. ^bNumbering of genotypes

according to Fischer-Le Saux et al. (1998). (Modified from Fischer-Le Saux et al., 1999b.)

Consequently, species and subspecies among *Photorhabdus* were delineated by applying a polyphasic approach, combining 16S rDNA, DNA-DNA hybridization and phenotypic data (Fischer-Le Saux et al., 1999b). The species are: a) *P. luminescens* containing the type strain and the symbiotic strains of ubiquitous and/or warm-region nematodes (max. growth at 35–39°C), b) *P. temperata* containing exclusively the symbiotic strains of temperate region nematodes (max. growth at 33–35°C) and c) *P. asymbiotica* originating from clinical samples from the United States. On the basis of 16S rDNA sequencing, the new Australian clinical strains (Peel et al., 1999) will probably constitute a new species (R.J. Akhurst et al., unpublished observation). The one non-luminous strain (Akhurst and Boemare, 1986c) probably is yet another species (Akhurst et al., 1996).

Within *P. luminescens* and *P. temperata*, subgroups of strains shared very high DNA-DNA hybridization values and δT_m s lower than 1.5°C,

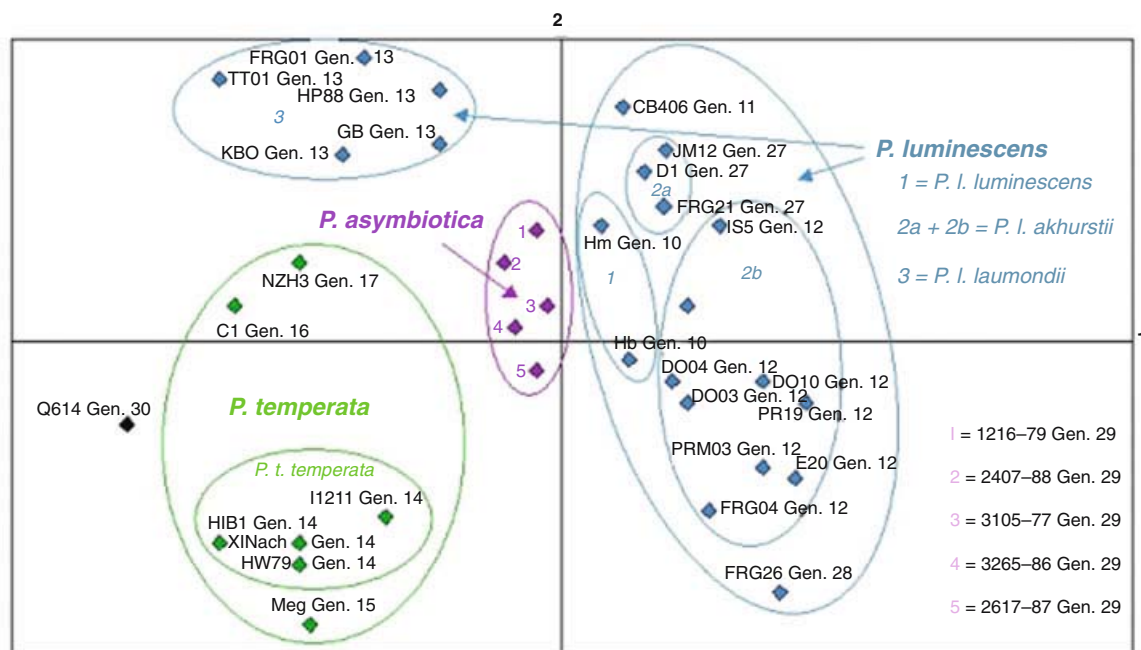

Fig. 6. Multivariate correspondence analysis of phenotypic data from *Photorhabdus* strains. This Q-R reciprocal analysis used the software Statlab (SLP®) taking into consideration only the physiological and biochemical characters scored as variable. The strains are positioned in the A space defined by the two first components. Strains with their PCR-RFLP genotype number (Fischer-Le Saux et al., 1998) are indicated at their position in the mathematical space. The corresponding species and subspecies are encircled. Only one unclassified strain is noted; Q614 (black spot) is a wild-type non-luminous *Photorhabdus* (Akhurst and Boemare, 1986c). Analysis of the inverted matrix (R analysis) shows that the first component is mainly supported by variables of growth temperature and DNase, explaining that the “warm” strains of *P. luminescens* subsp. *luminescens* and *P. luminescens* subsp. *akhurstii* are on the right side of the representation while the “temperate” strains are on the left side. Note that *P. asymbiotica* (pink spots) is a “consensual group” in the middle of the space (see also Fig. 7) near *P. luminescens luminescens* (cf. remark in Fig. 4 legend). Analysis used data published by Fischer-Le Saux et al. (1999b).

and were separated by stable 16S rDNA branching (Figs. 4 and 5). Consequently, *P. luminescens* was divided into three subspecies: *P. luminescens* subsp. *luminescens* (containing the type strain and strains associated with nematodes from the Brecon subgroup of *H. bacteriophora*), *P. luminescens* subsp. *laumondii* (containing strains associated with the HP88 subgroup of *H. bacteriophora*) and *P. luminescens* subsp. *akhurstii* (containing strains associated with *H. indica*). Similarly, a subspecies within *P. temperata* containing strains associated with the Palaearctic subgroup of *H. megidis*, and containing the type strain, was proposed as *P. temperata* subsp. *temperata*. As more strains become available, other subspecies will be defined in *P. temperata* especially for the Nearctic subgroup of *H. megidis*.

GENUS CHARACTERISTICS Cells of this genus (Thomas and Poinar, 1979; Boemare et al., 1993) are asporogenous and rod-shaped (0.5–2 by 1–10 µm). Cell size is highly variable within and between cultures with occasional filaments up to 30 µm long. In the last stage of exponential growth and during the stationary growth period,

spheroplasts may occur with an average of 2.6 µm in size (10–20% of cell population), resulting from the partial disintegration of the cell wall. Proteinaceous protoplasmic inclusions are synthesized inside a high proportion of cells (50–80%) during the stationary period. Cells are Gram negative, motile by means of peritrichous flagella, and facultatively anaerobic, having both a respiratory and a fermentative type of metabolism. Optimum growth temperature is usually ca. 28°C; some strains grow at 37–38°C. Most strains produce pink, red, orange, yellow or green-pigmented colonies on nutrient agar, and especially on rich media (tryptic soy agar, egg yolk agar). Luminosity (usually detectable by the dark-adapted eye) varies in intensity within and between isolates and may only be detectable by a photometer or scintillation counter in some isolates; only one non-luminous isolate is known among approximately 150 reported strains. Spontaneous phase shift occurs in subcultures, inducing the appearance of phase II clones (see Physiology/Phase Variation). The latter are characterized by considerably less neutral red adsorption on MacConkey agar, production of

antibiotics, and other properties usually exhibited by wild clones (named "phase I variants") freshly isolated from the natural environment. Cells do not reduce nitrate and are proteolytic for gelatin, positive for catalase and negative for oxidase, *O*-nitrophenyl- β -D-galactopyranoside (ONPG), Voges-Proskauer, arginine dihydrolase, lysine and ornithine decarboxylase. Proteolytic for gelatin. Most strains will hemolyze sheep and/or horse blood, some producing an unusual annular hemolysis on sheep blood at 25°C. All strains are lipolytic on Tween 20, and many are lipolytic on Tweens 40, 60, 80 and/or 85, as well. Cells produce acid from glucose (without gas), fructose, D-mannose, maltose, ribose, and *N*-acetylglucosamine, but only weakly from glycerol. Fumarate, glucosamine, L-glutamate, L-malate, L-proline, succinate and L-tyrosine are utilized as sole carbon and energy sources. Biochemical identification of *Photorhabdus* is summarized in Table 2. The mol% G+C of the DNA is 43–45 (*P. luminescens* strain Bd).

The American Type Culture Collection has the type strain (Hb) under accession number [ATCC 29999]. Unfortunately, it appears that the type strain of both the genus (*Photorhabdus*) and the species (*P. luminescens* strain Hb) is not a good representative of the *Photorhabdus* isolates, in as much as none of the numerous new isolates have been found to belong to this taxon. So far, strain Hm remains the only one closely related to the type strain Hb. The European Molecular Biology Laboratory (EMBL) accession number of the 16S rRNA gene sequence of the strain DSM 3368 (paratype of [ATCC 29999]; Rainey et al., 1995) is X82248.

PHOTORHABDUS LUMINESCENS The species characteristics of *Photorhabdus luminescens* (lu.mi.nes'cens. M.L. pres. part. *luminescens*, luminescing; for its luminescence; Thomas and Poinar, 1979; Boemare et al., 1993) are listed in Table 2. Cells are large rods (2–6 by 0.5–1.4 μ m). There are two phase variants (I and II), both luminous, but phase I has luminescence more than 100-fold greater than phase II. Maximum growth in nutrient broth occurs at 35–39°C. Strains are indole positive. Whereas some strains acidify mannitol, most are weak acid producers from fructose, *N*-acetyl-glucosamine, glucose, glycerol, maltose, mannose, ribose and trehalose. Protein inclusions found in the protoplasm of phase I cells are poorly produced in phase II cells. The natural habitat is in the intestinal lumen of entomopathogenic nematodes of *Heterorhabditis bacteriophora* (Brecon and HP88 subgroups), and of *Heterorhabditis indica*. *Photorhabdus luminescens* is divided in three subspecies. Accession numbers of type strain Hb and of the 16S rRNA gene sequence are given above.

PHOTORHABDUS LUMINESCENS SUBSP. LUMINESCENS The subspecies characteristics of *Photorhabdus luminescens* subsp. *luminescens* (Fischer-Le Saux et al., 1999) are listed in Table 2. Maximum growth in nutrient broth occurs at 38–39°C. Cells are positive for esculin hydrolysis, weakly positive for indole, and negative for DNase, tryptophan deaminase and urease. They produce annular hemolysis on sheep and horse blood agars. Cells use mannitol, not DL-lactate, as sole source of carbon and energy. This subspecies is symbiotically associated with nematodes from the Brecon subgroup of *H. bacteriophora*, the type species of the genus *Heterorhabditis* (Poinar, 1976). See accession numbers of type strain Hb and of the 16S rRNA gene sequence above.

PHOTORHABDUS LUMINESCENS SUBSP. LAUMONDII The subspecies characteristics of *Photorhabdus luminescens* subsp. *laumondii* (lau.mon'di.i. M.L. gen. n. *laumondii* of Laumond; referring to Dr. C. Laumond, a major contributor to the use of entomopathogenic nematode/bacterial complexes for insect pest control; Fischer-Le Saux et al., 1999) are listed in Table 2. Maximum growth in nutrient broth occurs at 35–36°C. Cells are positive for esculin hydrolysis, indole and DNase, mostly positive for urease and variable for tryptophan deaminase. They show total hemolysis on sheep and horse blood agars (the *Photorhabdus* annular reaction is rare) and do not use L-fucose, DL-glycerate, DL-lactate or mannitol.

Symbiotically, this subspecies (isolated in South and North America, southern Europe and Australia) is associated with nematodes of the HP88 subgroup of *H. bacteriophora*, which is evidenced by the binding of the satellite DNA probe of the nematode strain HP88 (provided by the team of Dr. C. Laumond; Grenier et al., 1996).

Type strain TT01 is held in the Collection of l'Institut Pasteur under accession number CIP 105565. The EMBL accession number of the 16S rRNA gene sequence is [AJ007404].

PHOTORHABDUS LUMINESCENS SUBSP. AKHURSTII The subspecies characteristics of *Photorhabdus luminescens* subsp. *akhurstii* (ak.hurs'ti.i. M.L. gen. n. *akhurstii* of Akhurst; referring to Dr. R. Akhurst, a major contributor to the bacteriological symbionts of entomopathogenic nematodes) are listed in Table 2. Maximum growth in nutrient broth occurs at 38–39°C. Esculin hydrolysis is positive, tryptophan deaminase and DNase negative, urease and indole variable. Annular hemolysis is observed on sheep blood agar, and in some strains, on horse blood

agar. Utilization of DL-lactate as sole source of carbon is variable and weak when positive. Mannitol is used (producing acid) and DL-glycerate not used.

Symbiotically, this subspecies is associated with the nematode *H. indica* isolated in warm regions; the first strain (strain D1) was isolated from Australia (Darwin, Northern Territory) by Dr. R. Akhurst.

Type strain FRG04 is held in the Collection of l'Institut Pasteur under accession number CIP 105564. The EMBL accession number of the 16S rRNA gene sequence is AJ007359.

THE SUBSPECIES *PHOTORHABDUS TEMPERATA*

The species characteristics of *Photorhabdus temperata* (tem.pe.ra'ta, L. fem. part. adj. *temperata*, moderate, so named because this species grows at moderate temperature; Fischer-Le Saux et al., 1999) are listed in Table 2. Cells are large rods (2–6 by 0.5–1.4 µm). Two phase variants occur, both of them highly luminous. Maximum growth in nutrient broth occurs at 33–35°C. Strains are positive for DNase, mostly positive for esculin hydrolysis and tryptophan deaminase, mostly negative for indole, and variable for urease. Acid is produced from fructose, *N*-acetylglucosamine, glucose, mannose and ribose; acid production from glycerol and maltose is weak. Protein inclusions are in protoplasm of phase I and II cells, but poorly produced in phase II cells. Annular hemolysis often occurs on sheep and horse blood agars. Most strains use DL-glycerate, and not DL-lactate as sole source of carbon. However, a few strains use mannitol.

The natural habitat is in the intestinal lumen of entomopathogenic nematodes of *Heterorhabditis megidis*, of the NC subgroup of *H. bacteriophora* and of *H. zealandica*.

Type strain XINach is held in the Collection of l'Institut Pasteur under accession number CIP 105563. The EMBL accession number of the 16S rRNA gene sequence is {AJ007405}.

PHOTORHABDUS TEMPERATA SUBSP. *TEMPERATA*

The subspecies characteristics of *Photorhabdus temperata* subsp. *temperata* (Fischer-Le Saux et al., 1999) are listed in Table 2. Cells are large rods (2–6 by 0.5–1.4 µm). Two phase variants and occasionally several intermediate forms occur, all of which are luminous. Maximum growth in nutrient broth occurs at 34°C. Cells are indole negative, DNase positive, esculin hydrolysis and tryptophan deaminase variable, and mostly urease negative. Annular hemolysis occurs on sheep and horse blood agars in most isolates. Strains use DL-glycerate and L-fucose, and not DL-lactate and mannitol, as the sole source of carbon.

The natural habitat is in the intestinal lumen of entomopathogenic nematodes of the Palaearctic subgroup of *H. megidis*. See above for accession numbers of the type strain XINach and 16 rRNA gene sequence.

PHOTORHABDUS ASYMBIOTICA The species characteristics of *Photorhabdus asymbiotica* (a.sym.bio'ti.ca., Gr. pref. *a*, not; M.L. adj. *asymbioticus*, -a, -um, living together; M.L. fem. adj. *asymbiotica*, not symbiotic; Fischer-Le Saux et al., 1999) are listed in Table 2. Cells are rod shaped (2–3 by 0.5–1.0 µm) and produce a yellow or brown pigment. Maximum growth in nutrient broth occurs at 37–38°C. No phase I isolates have been detected, and isolates never adsorb dyes and sometimes weakly produce antibiotics. Cells are negative for lecithinase on egg yolk agar, positive for urease, esculin hydrolysis and Christensen's citrate, but weakly positive for Simmons' citrate. They are negative for tryptophan deaminase, indole and DNase. Acid is produced from fructose, *N*-acetylglucosamine, glucose, maltose, mannose and ribose, but only weakly from glycerol. Protein inclusions are poorly produced. Tween 40 esterase is variable. Annular hemolysis occurs on sheep and horse blood agars. Cells do not use L-fucose, DL-lactate or mannitol.

Natural habitat is uncertain. All isolates are obtained from human clinical specimens. Strain 3265-86 (ATCC 43950) is the designated type strain, as suggested previously by Farmer et al. (1989).

The EMBL accession number of the 16S rRNA gene sequence (Szallás et al., 1997) is {Z76755}.

Habitat

In natural conditions, cells of symbiotic *Photorhabdus* are carried in the intestinal lumen of the free-living dauer stage of *Heterorhabditis* (often referred to as the infective juvenile) and insects infected by these nematodes. The bacterial cells are stored and do not multiply in the gut of the dauer host; this is a nonfeeding stage. When infective juveniles infect an insect, they release their symbionts into the body cavity of the insect prey (Fig. 2). Exceptionally, a few *Photorhabdus* strains may be experimentally infective per os (Ragni et al., 1996), some of them possessing entomotoxins acting orally (Bowen et al., 1998b; Guo et al., 1999; see Applications in this Chapter). Nevertheless, natural *Photorhabdus* septicemia without nematode help has not yet been reported from insect sampling. However, it is notable that such collections would be difficult to recover from nature. Whatever the mode of penetration,

when *Photorhabdus* gain entry into the body cavity of the insects, the bacterial cells multiply inducing toxemia and septicemia and the insect dies. Entomopathogenic nematode-infected insect cadavers do not putrefy and the nematode reproduction occurs in a sort of “bag” where the integrity of the cuticle of the insect cadaver seems to be a major barrier to external saprophages. In addition, several antimicrobial barriers acting in the body cavity of the insect contribute by suppressing microbial competitors. *Photorhabdus* produces both antibiotics (see Physiology in this Chapter) possessing a wide spectrum of activity (Akhurst, 1982a; Li et al., 1995; McInerney et al., 1991a; McInerney et al., 1991b; Paul et al., 1981; Richardson et al., 1988; Webster et al., 1998) and bacteriocins acting against closely related species (Baghdiguian et al., 1993; Boemare et al., 1992; Boemare et al., 1997a). These products have been identified from in vitro cultures, and also from in vivo analyses (Hu et al., 1998b), strongly indicating their role in the prevention of bacterial and fungal putrefaction of cadavers. Consequently the carcass is a sort of natural monoxenic microcosm that produces an apparent “mummification.” Nematodes reproduce inside and feed on the insect remains as metabolized by the symbiotic bacteria and also on the bacterial biomass. When the dauers escape the insect cadaver to search for new prey, they carry the symbiont in their gut, ensuring the vertical transmission of the mutualistic association. Although the nematode hosts are the natural vectors of symbiont propagation in the insects, in nutritional terms the *Photorhabdus* associated with nematodes might be considered entomophilic, rather than nematophilic, microorganisms.

However, *P. asymbiotica* is associated with human clinical specimens, not nematodes. These human clinical isolates are the only free-living members so far isolated from the genus. The life cycle of the clinical strains of *Photorhabdus* is much less certain. They have been isolated from five clinical sources in the United States (Farmer

et al., 1989) and five recently in Australia (Peel et al., 1999). Isolations were variously made from tissue, blood and sputum samples. No definite route of infection has been established; two patients reported spider bites prior to the infection and a third reported the possibility of a spider bite, but no definite connection between bite and infection has been made. Although some patients may have been immunocompromised, this was definitely not the case for at least two of the Australian patients. These clinical isolates were all cultivable on standard media at 37°C. Three of the four tested isolates exhibited the annular hemolysis on sheep blood agar at 25°C. By the time they were identified, all were phase II cultures (see Physiology/Phase Variation in this Chapter); it is not known whether they were originally isolated in phase II form.

COSPECIATION When the bacterial taxonomic results are compared with the taxonomic data of the host nematodes, a relatedness of the two taxonomic structures is noted, and a phenomenon of cospeciation between bacterium and nematode genera is implied (Table 3). The apparent exceptions do not fundamentally modify the concept because they are essentially the result of taxonomic confusions in the subgroups of *Heterorhabditis bacteriophora*. This species is widely distributed throughout the world, and with the use of more precise methods, nematological taxonomists will probably delineate subspecies. A phenomenon always seems to be in progress: the coevolution between both partners of the symbiosis. How is the specific association between bacteria and nematode maintained? It is likely that signal compounds are involved in the recognition for both partners, and there are indications of a specific attachment by the bacteria to the host cells. When leaving the insect cadaver, dauer larvae reinitiate the symbiosis by the recruitment of symbiont cells, which do not multiply inside the larvae primarily because of the lack of suitable nutrients. So this special association, where bacteria are not digested and are actually very well

preserved, suggests a special behavior of the dauer larvae, and a special quiescent physiology of the bacteria.

An exciting report of Poinar (1993) suggested that *Heterorhabditis* evolved from a marine ancestor. On the basis of biological, taxonomic and ecological arguments the genus *Heterorhabditis* would come from a *Pellioiditis*-like-ancestor in an arenicolous marine environment. As it seems likely that its symbiotic bacterium would have obtained the *lux* genes by horizontal genetic transfer from marine bacteria, the symbiosis may have originated at the seashore interface. *Photorhabdus luminescens* subsp. *akhurstii* isolated from *H. indica*, restricted to the sandy beaches of the Caribbean basin (Constant et al., 1998), may be a good example. In other parts of the world where complexes of *H. indica* and *P. luminescens* subsp. *akhurstii* also have been isolated, they were found under (or linked to) the sea that in geological times covered the Northern Territory in Australia, Nile Delta in Egypt and Negev Desert in Israel, except in India where they were found inland.

On some rare occasions other bacteria have been isolated from *Heterorhabditis* with *Photorhabdus*, for instance the genus *Ochrobactrum* (Babic et al., 2000) or the genus *Providencia* (Jackson et al., 1995). For all the nematodes sampled and on the basis of 16S RNA genotype and phenotypic properties, the *Ochrobactrum* isolates were correlated with their geographical origin, whereas the corresponding *Photorhabdus* symbiont was only correlated with their host's genotype (Babic et al., 2000). This shows the absence in the former case, and the presence in the latter case, of a cospeciation. Moreover the *Ochrobactrum* (and *Providencia*) probably came from an intercuticular location in contrast to *Photorhabdus*, which comes from the intestine of the host-nematode (see Isolation/Isolation of Other Isolates in this Chapter).

Isolation

ISOLATION OF SYMBIOTIC AND NONSYMBIOTIC STRAINS OF PHOTORHABDUS Three methods have been used for isolating *Photorhabdus* from nematodes. The "hanging drop" uses a sterile drop of insect hemolymph to which surface-disinfected dauer-stage *Heterorhabditis* are added (Poinar and Thomas, 1966b). The nematodes exsheath their old cuticles in the hemolymph drop and commence development, releasing their symbiont, which can be subcultured after about 24 h. A second method is to collect under sterile conditions a drop of insect hemolymph from an insect 24 h after infection by *Heterorhabditis*, and to streak it onto nutrient agar. The third method is to crush about 100 surface-disinfected dauer-

stage *Heterorhabditis* and to streak the macerate onto nutrient agar (Akhurst, 1980). This last method is the most rigorous method for assessing the microflora of the intestine of entomopathogenic nematodes, provided that a suitable control on the effectiveness of the surface disinfection is employed. The three methods have revealed the occurrence of *Photorhabdus* in every *Heterorhabditis* sp.

Human clinical isolates of *P. luminescens* have been variously obtained from open wounds, fluid aspirated from unerupted lumps, blood and sputum. These clinical isolates can be cultured at 37°C.

ISOLATION OF OTHER BACTERIA FROM HETERORHABDITIS The presence of secondary bacteria occurring together with the natural symbiont in some samplings of *Heterorhabditis* is noteworthy (see Habitat/Cospeciation in this Chapter). For example, in the case of *H. indica* (Babic et al., 2000), it is easy to discriminate *Ochrobactrum* by simple bacteriological tests (for positive oxidase and nitrate-reductase, for oxidative metabolism) from secondarily developed (see Physiology/Phase Variation in this Chapter) *Photorhabdus* variants (Wouts, 1990), small colony variants (Hu and Webster, 1998a), or intermediate forms of phase variants (Gerritsen et al., 1995). It was believed that these bacteria are carried in the space between the L2 and L3 cuticles and are isolated from infective juveniles when they are not adequately exsheathed during the disinfection of the nematode larvae. The conclusion that these bacteria are occasionally present in the nematodes without any role in the association is quite reasonable (Babic et al., 2000).

Identification

The taxonomic work necessary to characterize the species requires a long time for collecting the largest possible sample of strains to ensure adequate representation of the biodiversity of the genus and to permit conduct of the polyphasic analyses (see Taxonomy in this Chapter). Bacteriologists have to propose practical methods to identify new isolates more rapidly. This problem is not easy with *Photorhabdus*, which exhibits few positive responses with the classical phenotypic tests used for Enterobacteriaceae. Even if most of the responses are negative, some phenotypic tests must be conducted to confirm the genus identification.

The conventional methods for other Enterobacteriaceae are used to identify the *Photorhabdus* strains, but all biochemical tests are routinely conducted at 28°C and checked after 3–5 days of incubation. Discriminative characters are summarized in Table 2. Light microscopic examina-

tion of the rods at beginning of the stationary period of a culture is particularly notable: there are large, motile (by peritrichous flagella), Gram-negative rods (average 3–5 by 1–1.5 μm), sometimes up to 10 μm long, containing highly diffractive protoplasmic inclusions.

Photorhabdus strains are easily distinguished phenotypically from *Xenorhabdus* spp. because luminescence and catalase, both physiologically very significant characters, are positive for *Photorhabdus* and negative for *Xenorhabdus*. Urease in most *Photorhabdus* strains is positive, and assimilation of DL-lactate is negative for *Photorhabdus*; annular hemolysis on sheep blood agar at 25°C is only observed with *Photorhabdus* strains.

Luminescence does not cause confusion with the light-emitting marine bacteria of other families. *Photorhabdus* is differentiated from *Vibrio*, *Alteromonas* and *Photobacterium* by having peritrichous, nonpolar, flagella and in not requiring sodium ions for growth. Luminescence for most phase I variants (see Physiology/Phase Variation in this Chapter) can be checked in a darkroom after 10 min for dark-adaptation of eyes. To assess absence or weakness of light production in the phase II variants, a scintillation counter, a fluorimeter or a photomultiplier must be used. A loopful of an agar culture of each phase-variant culture is suspended in 10 ml of distilled water in a scintillation vial for immediate counting with a fully opened window setting (Grimont et al., 1984).

Another important phenomenon is the phase variation that essentially appears during in vitro culture (see Physiology/Phase Variation in this Chapter). Details of the techniques for identifying the phase variants have been summarized recently (Boemare et al., 1997b). The essential points are the following. Adsorption of dyes as described by Akhurst (1980) is the most convenient test to characterize the phase variants. MacConkey agar, or better still MacConkey agar without the bile salts, is a good medium for distinguishing phase I (red colonies) and phase II (off-white or yellow) variants (Boemare and Akhurst, 1988). On the nutrient bromothymol blue agar (NBTA) NBTA medium described by Akhurst (1980), the adsorption of bromothymol blue by *Photorhabdus* may be confused by the pigmentation of strains, and the resulting color of the clones can be difficult to distinguish. As most *Photorhabdus* are pigmented, growth on nutrient agar is often sufficient to differentiate clones of the variants, which differ significantly in not only pigmentation but also colony morphology, with phase I mucoid and convex and phase II non-mucoid and flattened. To test antibiotic production by *Photorhabdus*, clones of both variants are spot-inoculated on nutrient agar plates. After growth (generally 48 h later),

cultures are killed by chloroform vapor (30 min) and covered by fresh nutrient semisolid agar (0.6%) inoculated with a bacterial indicator such as *Micrococcus luteus* (Akhurst, 1982a). The inhibition halos of the indicator culture denote the phase I variants.

Antibiograms (Bauer et al., 1966) must be done at 28°C and incubated for 3 days to observe clear zones. *Photorhabdus* have large zones of inhibition around disks impregnated with nalidixic acid, gentamycin, streptomycin, kanamycin, tetracycline, and chloramphenicol, but none around penicillin. Resistance to colistin, ampicillin, carbenicillin and cephalothin is variable from strain to strain (Farmer, 1984). It is interesting to note that one patient infected with an isolate sensitive to gentamycin in vitro did not respond to gentamycin treatment (M. Peel, personal communication). The major cellular fatty acids of *Photorhabdus* are C_{16:0} and C_{18:1}, with C_{i-15}, C_{i-17} and C_{16:1} being major components in some strains (Janse and Smits, 1990; Suzuki et al., 1990). Ubiquinone-8 is the respiratory quinone in all strains (Suzuki et al., 1990).

In addition to phenotypic tests, some other simple positive and reliable tests are needed to identify *Photorhabdus* strains. These last four years, molecular probes useful for *Photorhabdus* ribotyping have identified defining restriction patterns specific for each group by using PCR-RFLP of the 16S rRNA genes. Pütz et al. (1990) initiated the use of the variable region of *Photorhabdus* and *Xenorhabdus* 16S rRNA genes to prepare oligonucleotide probes for the ribotyping of both genera, and Ehlers and Niemann (1998a) proposed to extend more precisely this method for *Photorhabdus*. Probes were prepared by PCR and amplified from a primer chosen in the variable region at positions 450–480 (*E. coli* numbering) and a primer from a region highly conserved at the positions 795–755 according to Stackebrandt and Goodfellow (1991). Thus, Ehlers and Niemann (1998a) defined a “type” probe for identifying the type species of the genus, a “tropicus” probe for symbionts from tropical nematodes, and a “temperatus” probe for the symbionts of nematodes from temperate climates. Today more than 22 total and 28 partial 16S-rDNA sequences are available on the gene databases covering most of the diversity of the *Photorhabdus*, allowing one to check the specificity of such variable regions for each species or subspecies or both. Some of the results (Table 4) are in accordance with the definition of a subspecies, with sequences belonging to a given subgroup showing the same variable region. This is the case for the “temperatus” probe, which has a specific sequence identical to sequences of several of the Palaearctic strains and to the sequence of *Pho-*

^aCollected from gene databases (updated April 2000), the sequences have been selected and aligned with algorithms BLAST (Altschul et al., 1997) and CLUSTAL (Thompson et al., 1997). ^bThe variable region with its conserved flanking parts is only represented from positions 440 to 490 (*E. coli* numbering).

torhaddus temperata subsp. *temperata*. The “type” probe also should be useful for correcting the discrepancies between several registered sequences (Table 4) to establish the true sequence corresponding to the type species *P. luminescens* subsp. *luminescens*. These discrepancies are due probably to the use of a strain that was not the correct type strain. This will be defined shortly. As only two strains (Hb and Hm strains) have currently been recognized as belonging to the type species (see *P. luminescens luminescens*), this probe does not present a big problem, except to confirm the separate phylogenetic position of the type species. Conversely, the “tropicus” probe is not sufficiently specific because many base substitutions have been

detected among the corresponding sequences of the "tropical" strains (Table 4). However, the method seems to be very promising for providing useful tools to identify subspecies when the appropriate sequence of the variable region is chosen accurately. As proposed by Ehlers and Niemann (1998a), "heliothisis" (a probe for identifying another subgroup [not yet identified] of *P. temperata*, particularly the symbiont NC1 of *H. bacteriophora* [= *heliothisis*]), the "Wisconsin" strains (a probe for the clinical strains of *P. asymbiotica* from the United States) and perhaps one for the Australian strains can be provided shortly.

Brunel et al. (1997) described another fast method using the polymorphism of the 16S

rRNA genes for identifying the diversity of the *Photorhabdus* and *Xenorhabdus*. (See *Photorhabdus*/Taxonomy and *Xenorhabdus*/Taxonomy in this Chapter) Fischer-Le Saux et al. (1998) applied this PCR-RFLP method (Fig. 1). Based on the total amplified sequence of the 16S ribosomal genes, the method provides reference restriction patterns for identifying other isolates. The reliability of results obtained with these genotypes and those from the previously described probes (Ehlers and Niemann, 1998) is at present uncertain. The latter could be improved by the choice of more specific variable sequences covering all the *Photorhabdus* biodiversity. Consequently, both molecular probes for and PCR-RFLP analysis of the 16S rRNA genes promise to be efficient tools for rapid identification of *Photorhabdus* isolates.

Cultivation

In vitro subcultures from fresh isolates can be obtained without major difficulty. *Photorhabdus* are mesophilic bacteria able to grow between 15 and 35°C, and some strains at 37–38°C. Subculturing and all biochemical tests should be undertaken around the optimal temperature of 28°C. Usually, nutrient agar or Luria-Bertani agar are sufficient for growth. On minimal media, nicotinic acid, *para*-aminobenzoic acid, proline, tyrosine and serine are required as growth factors, the mix of growth factors varying between strains (Grimont et al., 1984). Minimal medium II (BioMérieux®) contains all the necessary requirements to test utilization of organic compounds.

Preservation

The standard methods of freeze-drying, or low temperature storage (liquid nitrogen or at –80°C) used for Enterobacteriaceae, are also useful for long-term storage of *Photorhabdus* strains; –20°C is unsatisfactory. Cultures do not survive more than few months in broth or on agar plates at room temperature, and phase variation (see Physiology/Phase Variation in this Chapter) is likely to occur in this time. Cultures can be routinely maintained for one month at 15°C, but storage at 4°C is unsuitable; to prevent phase variation, phase I clones have to be subcultured every week from the neutral red dye-adsorbing clones on MacConkey agar.

Physiology

PHASE VARIATION In *Photorhabdus*, the phase variants differ by many characters and this is demonstrated by using a multivariate correspondence analysis of the phenotypic data (Fig. 7). All

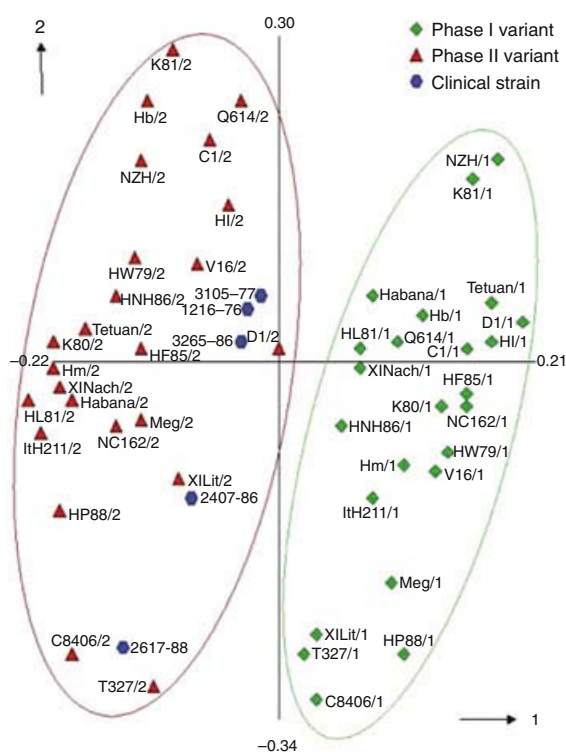

Fig. 7. Multivariate correspondence analysis of phenotypic data from *Photorhabdus* phase variants. All the data published by Akhurst and Boemare (1988) were treated as two-state (0,1) characters. Characters that were positive or negative for all isolates (i.e., that were not discriminative) were deleted (180/240). Here, the phase variants are positioned in the A space defined by the two first components using Q-R reciprocal analyses of the GENSTAT software (Alvey et al., 1980). Correspondence analysis from the contingency table used in Akhurst et al. (1996).

phase I variants are aggregated on the right of the figure, whereas phase II variants are on the left. Note that clinical strains are included in the cluster of phase II variants. No clinical isolates that resemble phase I nematode symbionts have ever been reported. When phase characters are excluded from the numerical analysis, the taxonomic clusters corresponding to the species are very well defined, meaning that phase variation is an infraspecific common phenomenon that does not essentially affect the taxonomy (Fig. 6).

Photorhabdus phase I variants are differently pigmented from phase II variants (e.g., red in phase I and yellow in phase II). Larger than phase II cells, phase I cells also are pleomorphic, comprising rods (80–90%) and spheroplasts (10–20%), and harbor protoplasmic inclusions (Boemare et al., 1983c; Fig. 8). Although the shift from phase I to II is spontaneous, it is remarkable that the wild dauer *Heterorhabditis* almost exclusively harbor phase I *Photorhabdus* (Akhurst and Boemare, 1990). The role of phase

Fig. 8. Protoplasmic inclusions in *Photorhabdus*. (a) Transmission electron micrograph of *Photorhabdus temperata* strain NC1. Culture is in stationary growth on nutrient agar, fixed with 2.5% glutaraldehyde + 1% osmium tetroxide, and stained with uranyl acetate and lead citrate. Arrow = crystalline inclusion. Bar = 0.5 μ m. (b) Fast-freeze fixation and cryosubstitution of *Photorhabdus temperata* strain NC1. Culture is in stationary growth on nutrient agar. Piece of solid agar bearing bacterial colonies was freeze fixed by liquid helium at -260°C on pure copper, cooled, dehydrated by 100% ethanol, and substituted by infiltration with a cryocool for 3 days at -90°C . Sections were contrasted with uranyl acetate and lead citrate. Two types of crystalline inclusions (arrows) are shown. The corresponding structures similar to "myelinic" (m) membranes shown with strain Q614 (Fig. 8d) are poorly contrasted with this method (see Baghdiguian et al., 1993). Bar = 0.5 μ m. (c) Fast-freeze fixation and cryosubstitution of *Photorhabdus temperata* strain NC1. Culture is in stationary growth on nutrient agar. Specimen preparation was by the method described in legend to Fig. 6b. Membranes (m) of "myelinic" bodies are better visualized than they are in Fig. 8b (see Baghdiguian et al., 1993). Arrows = crystalline inclusions. Bar = 0.5 μ m. (d) Cell of nonluminous strain Q614 of *Photorhabdus* sp., fixed with 2.5% glutaraldehyde and 1% osmium tetroxide, and stained with uranyl acetate and lead citrate. Two types of crystalline inclusions (arrows) are shown in the protoplasm. Significance of the condensed material looking like fingerprints and similar to "myelinic" bodies visible in the two thirds of the protoplasm is not interpreted as yet. Bar = 0.5 μ m.

II variants is not evident and today the data to support a good explanation for their occurrence is unconvincing.

Phase change occurs during the in vitro stationary period of growth in a highly unpredictable manner (Akhurst and Boemare, 1990). The two phases of *Photorhabdus* differ significantly in respiratory activity (Smigielski et al., 1994b). After periods of starvation, phase II cells recommenced growth within 2–4 h of the addition of nutrients, compared with 14 h for phase I cells, indicating the former had more efficient nutrient uptake ability. Phase II variants may grow a little on complex media previously utilized by phase I variants (Akhurst and Boemare, 1990). How-

ever, although reciprocal phase change occurs in *Xenorhabdus*, conversion from phase II *Photorhabdus* to phase I has not been unambiguously demonstrated. Several intermediate colony forms, possessing at least some phase I properties, have been recorded (Gerritsen et al., 1992). However, it is not certain that these colonies were not mixtures of phase I and II cells, rather than truly intermediate. The only confirmed reversion to phase I occurred from intermediate variants not yet established as definitively phase II (Krasomil-Osterfeld, 1995). *Photorhabdus* phase II variants support the growth of their host nematodes very poorly. Consequently the phase traits of *Photorhabdus* are mainly involved in the growth and development of the *Heterorhabditis* nematodes and may be considered to be "symbiotic characters." However, both phases show a similar entomopathogenic effect and share all the other bacteriological properties of members of the genus.

PRODUCTION OF SECONDARY METABOLITES *Photorhabdus* phase I variants produce a variety of secondary metabolites, some of which have antimicrobial properties. The carcass is a sort of monoxenic microcosm where the symbionts eliminate competitive microorganisms by using several antibiotics (see Habitat in this Chapter) possessing a wide spectrum of activity (Li et al.,

1995; Paul et al., 1981; Richardson et al., 1988). Two chemical groups have been characterized: hydroxystilbenes and polyketides (anthraquinone derivatives; Table 5). Hu et al. (Hu et al., 1997; Hu et al., 1998b) purified these compounds and examined the conditions under which these secondary metabolites are produced both *in vivo* and *in vitro* culture using a strain of *P. temperata* that was a symbiont of *H. megidis*. Only one of the two identified stilbenes produced in the extract from nematode-bacterium infected insects is recovered from tryptic soy broth culture. An array of closely related polyketide derivatives is also produced by *Photorhabdus* in the insect larvae of *Galleria mellonella*. These pigments vary in the positioning and/or number of hydroxyl and methoxyl groups around the central anthraquinone ring structure (Hu et al., 1998b), and those that are antimicrobial are mentioned in Table 5. Their occurrence also varies according to *in vivo* or *in vitro* production. The available nutrients and the prevailing environmental conditions, undoubtedly have a significant effect on the difference in metabolite composition (Webster et al., 1998). These

antibiotics are most commonly active against Gram-positive bacteria, but some are effective against Gram-negative bacteria (see Applications in this Chapter).

Photorhabdus strains are the only terrestrial luminous bacteria known today. The chemical pathway for producing light is similar to the mechanism of marine bacteria (Frackman et al., 1990b; Frackman and Nealson, 1990a). The luciferase catalyzes the reaction in which reduced flavin mononucleotide (FMNH₂) and an aldehyde are oxidized to FMN, an acid and H₂O, and light is emitted at 490 nm. Conversely, the fatty acid reductase complex generates an aldehyde and the flavin oxidoreductase reduces FMNH₂. No satisfactory demonstration has yet been provided to explain the role of luminescence in this genus. An association between luminescence and virulence factors for the pathogenicity of *Vibrio harveyi* against *Penaeus monodon* has been noted (Manefield et al., 2000).

BACTERIOCINOGENY Unlike *Xenorhabdus* spp., no temperate phages have been yet characterized in *Photorhabdus* strains, although phage

tail-like bacteriocins have been observed by electron microscopy of culture supernatants (Baghdigui et al., 1993). They are different in size and shape than those of *Xenorhabdus* (Boemare et al., 1992). It is reasonable to think that they play also a role in the competition with closely related bacterial genera, as demonstrated for *Xenorhabdus* (Boemare et al., 1992; Thaler et al., 1995; Thaler et al., 1996; Thaler et al., 1997).

Genetics

Genetic studies, undertaken over these last ten years, examined several structural genes and attempted to identify the mechanism of phase variation (for a comprehensive review see: Forst et al., 1997; Forst and Neilson, 1996). Recently the characterization of genes encoding protein toxins that (when ingested) are active against insects was described (Blackburn et al., 1998; Bowen et al., 1998b), and two corresponding toxic proteins have been purified (Guo et al., 1999).

Several strains of *Photorhabdus* harbor megaplasmids for which no role or gene has been identified (Smigielski and Akhurst, 1994a). Megaplasmids in other species are known to contain genetic information necessary for symbiosis, pathogenicity and conjugation. *Photorhabdus* plasmids have not been further characterized or engineered to generate cloning vectors.

GENES AND PROTEINS Several genes have been identified in *Photorhabdus* strains (Table 6). The *lux* operon (*luxCDABE*), which encodes the proteins required for luminescence (Frackman et al., 1990b) has been characterized. The amino acid identity values for the corresponding proteins coded by the structural genes of the marine luminous bacteria *Photobacterium* and *Vibrio* are 62–85% for *lux A* and 47–59% for *lux B* (Johnston et al., 1990; Meighen and Szttnner, 1992). The regulatory genes for the *Photorhabdus lux* operon have not yet been identified (Szttnner and Meighen, 1990; Xi et al., 1991).

The operon coding for polynucleotide phosphorylase (Pnp), which degrades mRNA, and for

a ribosomal protein, RpsO, was cloned from the strain K122 (Clarke and Dowds, 1994). Regulation of expression of the *rpsO-pnp* operon is complex. The two genes are induced at low temperature.

A *malB* region with 53.5% identity to the equivalent *E. coli* gene was identified (Dowds, 1997). The maltose regulon of *E. coli* consists of genes involved in maltose uptake. The cloned region encompasses part of the *malE* and *malK* genes and the regulatory region between them. The intergenic region contains the control regions that respond to levels of maltose in the media and also to catabolite repression.

Phase I variants produce a pigment whose color varies according to the strain. The genes coding for the red anthraquinone pigment of the Hm strain have been cloned into *E. coli* (Frackman and Neilson, 1990a).

The genes *cipA* and *cipB* coding for the two types of protein crystals from the protoplasm of *Photorhabdus* (Boemare et al., 1983c; Couche et al., 1987b; Couche and Gregson, 1987a), have been characterized (Bintrim and Ensign, 1998). These genes have separate promoters and when expressed in *E. coli* resulted in inclusion body formation in the cells. Normally these genes are strongly expressed only by phase I variants (Boemare and Akhurst, 1988), so their inactivation induces changes in some other phase-related characters.

The *lip-1* gene of extracellular lipase was also cloned and sequenced (Wang and Dowds, 1993). It encodes a protein of 645 amino acids from which a hydrophobic leader sequence of 24 amino acids is removed during the processing in *E. coli*. Such a processing seems to be necessary for the secretion of other active proteins.

Toxin genes have been cloned from strain W14 (Bowen et al., 1998b). These genes encode large insecticidal toxin complexes with little homology to other known toxins. The toxin purified as a protein complex that has an estimated molecular weight of 1,000,000. It consists of a series of four native complexes at loci named *tca*, *tcb*, *tcc*, and *tcd*. Both *tca* and *tcd* encode complexes with high

Table 6. Identified genes and proteins from *Photorhabdus* strains.

oral toxicity for insects. Two purified native toxins A and B were found to be active in nanogram concentrations against insects. Two peptides present in toxin B could be processed in vitro from a 281-kDa protoxin by endogenous *P. luminescens* proteases (Guo et al., 1999). A smaller insecticidal protein (ca. 40 kDa) unrelated to the large toxin complex has also been identified in *Photorhabdus* and the cognate gene cloned (East et al., 1999).

The sequencing of the whole genome of strain TT01, which is in progress, will identify new genes, see the (<http://www.pasteur.fr/externe{Institut Pasteur}>) for further functional genomic studies.

REGULATION OF PHASE VARIATION Major changes in DNA structure do not appear to account for the phenotypic switches. No differences in plasmid profiles of the two phases have been detected. DNA-relatedness studies and restriction digests of total DNA indicated that the organization of the genome is the same in the two phases (Akhurst et al., 1992; Boemare et al., 1993; Frackman et al., 1990b; Wang and Dowds, 1991; Wang and Dowds, 1993).

DNA has been successfully transferred by means of transformation and conjugation. Modification systems such as methylation are commonly associated with restriction endonucleases that protect the genome from foreign DNA. Endonuclease activities have been detected in a range of *Photorhabdus* spp. and an isoschizomer of XhoI was purified from strain K80 of *P. luminescens* subsp. *laumondii* (Akhurst et al., 1992). Such a restriction-modification system is an obstacle for transformation and conjugation of *Photorhabdus* strains and explains the low frequency of transformants and transconjugants obtained. Nevertheless, Frackman and Nealson (1990a) reported the transformation of strain Hm by using competent cells from a modified CaCl₂/RbCl method, and Dowds (1997) used electroporation to transform with pBR322 and pHK17. Conjugation from *E. coli* to *Photorhabdus* strain K122 allowed transfer of the plasmids RP4 and pSUP104 (Dowds, 1997).

The molecular mechanism of phase variation remains uncertain. Some experiments to inactivate genes involved in phase variation have been successful and indicated that phenotypic phase characters can be altered in phase I variants or expressed in phase II variants. For instance inactivation of the crystal protein genes of strain NC1 produced a phase II phenotype (Bintrim and Ensign, 1998). The UV mutagenesis of phase II variants of strain K122 induced expression of phenotypic properties of the corresponding phase I variants (Wang and Dowds, 1993). The lipase gene transcription is initiated at the same

site in the two phases (Wang and Dowds, 1993) and lipase mRNAs accumulate to the same extent in the two phases, implying that gene expression in the phase II variant is repressed at a post-transcriptional level. In fact the lipase protein accumulates and is secreted to the same extent in the two phases. However the lipase protein is inactive in the phase II variant, as is the protease (Wang and Dowds, 1993). Lipase and protease are regulated at a post-translational level in the Irish K122 strain of *P. luminescens* (Wang and Dowds, 1993), whereas the *lux* genes are post-transcriptionally regulated in the Hm strain (Hosseini and Nealson, 1995). This contrasts with *X. nematophilus* in which the flagellin genes are not transcribed during phase II (Givaudan et al., 1996). These preliminary studies seem to indicate that phase-specific genes in *Photorhabdus* are regulated at a post-transcriptional, probably post-translational, level by a common control mechanism, a genetic level different from that in *Xenorhabdus*.

Ecology

Despite the intestinal location of *Photorhabdus*, which allows environmental contamination, their specificity for *Heterorhabditis* is a remarkable feature of this symbiosis (Boemare et al., 1997a; Forst et al., 1997). When microbial ecology studies are undertaken, using a simple and fast method of PCR-RFLP of 16S RNA (Brunel et al., 1997), a clear correspondence between *Photorhabdus* isolates and nematode species can be seen. From a total of 75 isolates identified in the Caribbean region (Fischer-Le Saux et al., 1998), two genotypes were associated only with *Heterorhabditis bacteriophora* and another two only with *Heterorhabditis indica*, although these four genotypes belong to the same DNA/DNA relatedness group.

Within the *Photorhabdus* genus, the maximum growth temperature appears to be a relevant taxonomic character defining a critical value for each subgroup (Table 2). It implies essential physiological adaptations in the enzymatic machinery of the bacteria and must therefore be considered as important for defining taxa. Moreover, if we examine the ecology of the corresponding strains, it is notable that the maximum growth temperature and the host species origin are correlated. Symbionts growing at temperatures up to 35–39°C are harbored by *H. bacteriophora* (Brecon, HP88 groups) and *H. indica* that occur in hot regions. Those that grow only up to 35°C are harbored by *H. megidis* (both its Palaearctic and Nearctic strains) and *H. bacteriophora* (NC group); all of these nematodes live in temperate climates. Thus, temperature tolerance appears to be an important property reflecting

a long-term adaptation to different climatic conditions.

Two ecological niches have been identified for nematode-symbiotic *Photorhabdus*: one is in the insect host as a metabolically active form and the other is in the gut of the nonfeeding dauer nematode as a quiescent form. The occurrence of nonsymbiotic clinical strains possessing the phase II properties of the nematophilic symbionts, and the remarkable differences in respiratory activity between the two phases of the symbiotic strains, suggest that the soil may be a third niche. However, recently reported experiments to test the symbiotic strains' ability to grow and survive in external environments indicate that they disappear within a few days (Morgan et al., 1997). *Photorhabdus* strains may enter into a nonculturable but viable survival strategy, as do *Aeromonas*, *Vibrio*, *E. coli* and *Salmonella* spp.

Epidemiology

All *Photorhabdus* strains examined to date have been reported to be entomopathogenic, the LD₅₀ usually being <100 cells when injected into hemocoel of the insect *Galleria mellonella* (Akhurst and Boemare, 1990; Akhurst and Dunphy, 1993; Farmer et al., 1989). *Photorhabdus asymbiotica* may also cause some human diseases (see Disease).

To test insect pathogenicity, 10², 10³ or 10⁴ cells (total count) from a 24-h broth culture are injected into final instar *Galleria mellonella* or *Spodoptera littoralis* larvae (Lepidoptera). The injected larvae should be placed on dry filter paper in Petri dishes and incubated at 25°C for 3 d. Most *Photorhabdus* spp. will kill <50% at a dosage of 10² cells; all will kill <50% at 10⁴ cells. Depending on the insect species tested, some differences in pathogenicity between *Photorhabdus* strains and phases may be noted. According to Bucher (1960), when the LD₅₀ is >10⁴ cells, the bacterium may be considered as entomopathogenic. To date, all *Photorhabdus* isolates, regardless of phase, have been reported to infect insects at a LD₅₀ > 10²–10³ cells by injection. Consequently *Photorhabdus* have to be considered as highly entomopathogenic. In addition some of them (strain W14, and an unnamed Italian strain) may be entomopathogenic by ingestion (French-Constant and Bowen, 1999; Ragni et al., 1996). The toxin produced is active on the insect digestive epithelium, not only from the gut lumen, but also from the body cavity (Blackburn et al., 1998; see Applications in this Chapter).

Disease

Photorhabdus has also been isolated from human wounds and blood in the United States

(Farmer et al., 1989) and more recently in Australia (Peel et al., 1999). None of the infections were lethal but some required weeks of treatment. Four American patients were elderly people or apparently immunocompromised; the other was a 45-year-old male who had suffered a spider bite. The bacterial strains, isolated from them and kept in the United States Centers for Disease Control and Prevention in Atlanta (CDC), were compared after the description of the symbiotic strains was published, and they were defined as a clinical group in the genus (Farmer et al., 1989), and now belong to *P. asymbiotica* (see Taxonomy in this Chapter). Among the four recent isolations in Australia, one of the Australian patients was definitely a victim of spider bite, and another may have been. None of the patients was immunocompromised; the one elderly patient made the fastest recovery. One case was the result of a disseminated infection, whereas the three others had a bacteremia or skin lesions (Peel et al., 1999). The possibility that spiders may vector infection by nonsymbiotic strains of *Photorhabdus* has yet to be tested.

Applications

Knowledge about the nutritional requirements provided by the symbionts would improve the mass production of the entomopathogenic nematodes for biological control of insect pests. In terms of symbiosis, this is one of the most exciting subjects related to these bacteria. During the industrial process, the quality of the symbiont inoculum, in terms of viability, phase I variant selection, and preservation from any other microbial contamination, must be maintained (Ehlers et al., 1998b; Ehlers et al., 1990). Several programs have been undertaken to define the key factors of the symbiosis; nothing significant has been reported to date. However it should be noted that academic access to this knowledge is difficult to obtain because the know-how of such industrial processes is kept secret. What biochemical compound(s) is/are released in the supernatants in the bioreactors during monoxenic nematode production? A "food signal," a term taken from *Caenorhabditis elegans* physiology, is produced by a German strain of *P. temperata*. Although not produced at the same strength as found in insects, the food signal has been characterized (Strauch and Ehlers, 1998). It induces the exit from the developmentally arrested dauer larvae, explaining the recovery of juveniles when they enter the insects. The food signal could be a special nutrient supplied by the bacteria to the nematode and/or a hormone controlling nematode development.

Some of the secondary metabolites have commercial potential in the pharmaceutical and agro-forestry industries (Webster et al., 1998). Among the isolates examined to date from *P. luminescens* subsp. *luminescens* and *P. temperata*, some of the anthraquinone pigments and the *trans*-stilbenes are antibacterial and the *trans*-stilbenes are antifungal, especially when the isolates are cultivated in vitro. This is of great interest to industry (Table 5).

Moreover, the occurrence of protein toxins produced by some *Photorhabdus* strains and acting orally against several insect species has recently enhanced the interest in these bacteria for biological control (Blackburn et al., 1998; Bowen et al., 1998b; Bowen and Ensign, 1998a; Guo et al., 1999). The toxin genes can be cloned and will be inserted into plant genomes, as with *B. thuringiensis* ("Bt"), used for producing transgenic plants toxic for insects. In addition, to overtake the first resistance observed in the target insects consuming these transgenic Bt plants, the insertion of both (Bt and *Photorhabdus*) toxin genes in the same plant can be envisioned (Ffrench-Constant and Bowen, 1999). This second field of industrial projects opens very promising biotechnology programs for the next ten years in plant protection. To date, six patents have been submitted (East et al., 1999; Ensign et al., 1997; Ensign et al., 1998; Kramer et al., 1999b; Ragni et al., 1996).

Genus *Xenorhabdus*

Phylogeny

Analyses of 16S rDNA sequences show that *Xenorhabdus* is most closely related to *Photorhabdus*. The next nearest phylogenetic neighbors are *Proteus vulgaris* and *Arsenophonus nasoniae* (Brunel et al., 1997; Fischer-Le Saux et al., 1999b; Liu et al., 1997; Suzuki et al., 1996; Szállás et al., 1997). Only limited 16S rDNA sequence data are available at this time, most *Xenorhabdus* species being represented by sequences from only one or two strains. However, *Xenorhabdus* can be distinguished from its nearest phylogenetic neighbor, *Photorhabdus*, by the sequence TTCG at positions 208–211 (*E. coli* numbering) of the 16S rDNA. *Photorhabdus* has a longer version (TGAAAG; Fischer-Le Saux et al., 1999b; Szállás et al., 1997). The PCR-RFLP analysis shows that of the 17 *Xenorhabdus* genotypes identified to date, 8 correspond to 5 species of *Xenorhabdus* and the remainder corresponds to some other, as yet undefined, species (Fig. 9).

Fig. 9. Phylogenetic tree from PCR-RFLP 16S rDNA genotypes of *Xenorhabdus*. The neighbor-joining method was applied to the 17 defined genotypes, from a total of 65 strains. The number of the genotype according to Fischer-Le Saux et al. (1998) is followed by the name of the representative strain. Defined symbiont species are indicated in red, and host nematodes in blue.

Taxonomy

NONMENCLATURE AND FAMILY LINKING The first symbiotic bacterium isolated from entomopathogenic nematodes was described as a new species "*Achromobacter nematophilus*" (Poinar and Thomas, 1965). With the rejection of the genus "*Achromobacter*" (Hendrie et al., 1974), this new species could not be accommodated within any existing genus. Thomas and Poinar (1979) described a new genus, *Xenorhabdus*, to accommodate the bacterial symbionts of entomopathogenic nematodes as two species, *X. nematophilus*, symbionts of the family Steinernematidae, and "*X. luminescens*," associated with the Heterorhabditidae; the latter was subsequently reassigned to the genus *Photorhabdus* (Boemare et al., 1993). *Xenorhabdus* have low DNA/DNA relatedness (4%) to the type species of the type genus in the family Enterobacteriaceae (Farmer, 1984) and lack nitrate reductase, which is positive for all other genera in this family. However, they do have the enterobacterial common antigen (Ramia et al., 1982) and phylogenetic analyses based on 16S rDNA (Brunel et al., 1997; Fischer-Le Saux et al., 1999b; Liu et al., 1997; Suzuki et al., 1996; Szállás et al., 1997) confirm their relatedness to the Enterobacteriaceae.

THE POLYPHASIC APPROACH TO GENUS AND SPECIES DELINEATION From a phenotypic study of bacterial symbionts of the Steinernematidae,

four groups were recognized within the genus, and the subdivision of *X. nematophila* into subspecies was proposed (Akhurst, 1983). A more comprehensive phenotypic study (Boemare and Akhurst, 1988) led to the elevation of the subspecies to species status, as *X. nematophila* (= *nematophilus*), *X. bovienii*, *X. poinarii* and *X. beddingii* (Akhurst and Boemare, 1988). *Xenorhabdus japonica* (= *japonicus*), symbiotically associated with *Steinernema kushidai*, was described later (Nishimura et al., 1994). DNA/DNA hybridization (Akhurst and Boemare, 2000; Akhurst et al., 1996; Boemare et al., 1993; Suzuki et al., 1990) and 16S rDNA analyses (Brunel et al., 1997; Fischer-Le Saux et al., 1998; Liu et al., 1997; Suzuki et al., 1996; Szállás et al., 1997) validated the inclusion of these five species in, and the exclusion of *P. luminescens* from, the genus (see Taxonomy in this Chapter).

DNA/DNA hybridization analysis indicates that there are (to date) more than the five *Xenorhabdus* species. Data have been recorded for some of the strains that would be assigned to new *Xenorhabdus* species (Boemare and Akhurst, 1988; Bonifassi et al., 1999; Fischer-Le Saux et al., 1998), but too few to warrant a decision on their taxonomic status. A recent multivariate analysis of phenotypic data (Bonifassi et al., 1999) from *Xenorhabdus* strains (Fig. 10) confirmed that some strains should be assigned

to several new species (e.g., the symbionts of *S. arenarium*, *S. puertoricense*, *S. riobrave*, *S. scapterisci* and *S. serratum*) that will be defined in due course (Table 7).

GENUS CHARACTERISTICS Cells are Gram-negative, asporogenous, rod shaped, 0.3–2 µm by 2–10 µm and occasionally have filaments 15–50 µm in length. Spheroplasts, averaging 2.6 µm in diameter, appear in the last third of exponential growth. Proteinaceous crystalline inclusions develop in a large proportion of cells in stationary phase cultures. Cells move by means of peritrichous flagella, and swarming may occur on 0.6–1.2% agar. These bacteria are facultatively anaerobic, with both respiratory and fermentative types of metabolism. Optimum temperature is usually 28°C or less; a few strains grow at 40°C. Acid (no gas) is produced from glucose; fermentation of some other carbohydrates is poor. Strains are catalase negative, DNase positive and protease positive. Nitrate is not reduced to nitrite. Most tests used to differentiate Enterobacteriaceae are negative. Lipase is detected with Tween 20 and egg yolk agar; most strains are lipolytic on Tweens 40, 60, 80 and/or 85. Phase shift occurs to varying degrees in stationary phase cultures, giving rise to phase II cells that lack dye adsorption, antibiotic production, protein inclusions and some other characteristics of

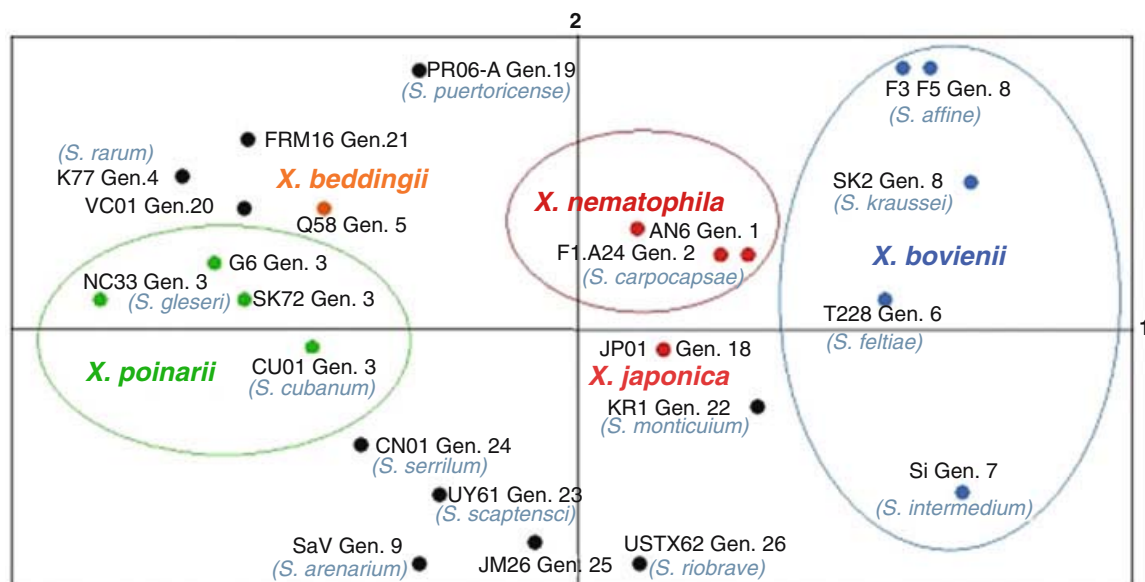

Fig. 10. Multivariate correspondence analysis of phenotypic data from *Xenorhabdus* strains. This Q-R reciprocal analysis used the software Statlab (SLP®) taking into consideration only the physiological and biochemical characters scored as variable. The strains are positioned in the A space defined by the two first components. Strain names with their PCR-RFLP genotype numbers (Fischer-Le Saux et al., 1998) are indicated at their position in the mathematical space. Those species represented by several strains are encircled. Host nematode species are indicated in blue between brackets for the isolated strains. Analysis of the inverted matrix (R analysis) shows that the first component is mainly supported by the growth-temperature variable, which is the reason “warm” strains of *Xenorhabdus* are on the left side while “temperate” strains are on the right side of the representation. Adapted from data published by Fischer-Le Saux et al. (1999a) and Bonifassi et al. (1999).

the phase I cells isolated from the natural environment. Biochemical identification of *Xenorhabdus* within the family Enterobacteriaceae is summarized in Table 7. The mol% G+C of the DNA is 43–50 (strain Bd). Strains are only found in the intestinal lumen of entomopathogenic nematodes of the family Steinernematidae and insects infected by these nematodes.

XENORHABDUS NEMATOPHILA The species characteristics of *Xenorhabdus nematophila* (ne.ma.tóphi.la. Modern entomological term *nematode*; Gr. adj. *phila*, loving or having affinity for; M.L. adj. *nematophila* nematode-loving; synonym: *Achromobacter nematophilus*; Poinar and Thomas, 1965; Thomas and Poinar, 1979) are listed in Table 7. No known isolates grow at temperatures in excess of 34°C. Neither phase I nor II colonies are pigmented. Most isolates are sensitive to furazolidone. Strains are found associated only with one species of nematode, *Steinernema carpocapsae*, but this association occurs around the world.

The mol% G+C of the DNA is 43–48 (strain Bd). Type strain number of the holotype is ATCC19061; paratype DSM3370. Genbank accession number of 16S rDNA is {D78009}.

XENORHABDUS BOVIENII The species characteristics of *Xenorhabdus bovienii* (bo.vi.en'i.i. M.L. gen.n. *bovienii*, of Bovien. Named for P. Bovien who first reported the presence of bacteria in the intestinal vesicle of a *Steinernema* species; Akhurst and Boemare, 1988) and *Xenorhabdus nematophilus* subsp. *bovienii* (Akhurst, 1983) are listed in Table 7. No growth occurs at 34°C; some strains will grow at 5°C. Strains are resistant to carbenicillin.

They are associated with several species of entomopathogenic nematode (*Steinernema feltiae*, *Steinernema intermedium*, *Steinernema kraussei* and *Steinernema affine*) in temperate regions.

The mol% G+C of the DNA is 44.3 (strain P1) and 46.9 (strain Bd). Type strain number of the holotype is UQM2210 (phase I of strain T228); paratype numbers are ATCC35271 and DSM4766. Genbank accession number of 16S rDNA is {X82254} and {D78007}.

XENORHABDUS POINARII The species characteristics of *Xenorhabdus poinarii* (poi.nar'i.i. M.L. gen.n. *poinarii*, of Poinar. Named for G.O. Poinar Jr. who made major contributions to the understanding of entomopathogenic nematode/bacterial interactions; Akhurst and Boemare, 1988) and *Xenorhabdus nematophilus* subsp. *poinarii* (Akhurst, 1983) are listed in Table 7. This is the most heat tolerant *Xenorhabdus*, with all strains growing at 36°C and some at 40°C. The intensity

of pigmentation in phase I varies from light to reddish brown. In some strains phase I cells do not produce antimicrobials; in some other strains, cells in both phases do.

In the United States, *X. poinarii* was first considered to be associated with only *Steinernema glaseri* (Akhurst, 1986b). A polyphasic approach, including phenotypic tests, restriction polymorphism analysis of PCR-amplified 16S rRNA genes, and DNA-DNA hybridizations with determination of the δT_m , was used to demonstrate that *S. cubanum* also harbors strains of *X. poinarii* (Fischer-Le Saux et al., 1999a). This bacterium is not pathogenic for most wax moth (*Galleria mellonella*) larvae unless associated with its nematode partner.

The mol% G+C is 42.6 (strain P1) and 49 (strain Bd). Type strain number of the holotype is UQM2216 (phase I of strain G); paratype numbers are ATCC35272, DSM4768. Genbank accession number of 16S rDNA is {X82253} (paratype DSM4768).

XENORHABDUS BEDDINGII The species characteristics of *Xenorhabdus beddingii* (bed.din'gi.i. M.L. gen. N. *beddingii*, of Bedding. Named for R.A. Bedding who made significant contributions to the development of *Xenorhabdus/Steinernema* associations for insect pest control; Akhurst and Boemare, 1988), first named *Xenorhabdus nematophilus* subsp. *beddingii* (Akhurst, 1986a), are listed in Table 7. All isolates grow at 34°C, and some at 38°C. Cells hydrolyze esculin. They are inhibited by cephaloridine and ampicillin. The brown pigmentation is not strong. Phase I is highly unstable, producing the very stable phase II. They are associated with two undescribed species of *Steinernema* from Australia, one of which may be *Steinernema longicaudum*, a described species from China.

The mol% G+C of the DNA is 45.5–50 (strains Bd and P1). Type strain number of the holotype is UQM2871 (phase I of strain Q58); paratype numbers are ATCC49542, DSM4764. Genbank accession number of 16S rDNA is {X82254} (paratype DSM4764).

XENORHABDUS JAPONICA The species characteristics of *Xenorhabdus japonica* (ja.po'ni.ca. M.L. adj. *japonica*, of Japan; Nishimura et al., 1994) are listed in Table 7. Cells do not grow at 37°C. Arginine dihydrolase activity is detected in phase II. Pigmentation is yellowish brown. This species is only known to be associated with *Steinernema kushidai* in Japan.

The mol% G+C of the DNA is 45.9 (strain P1). Type strain number of the holotype is IAM14265. Genbank accession number of 16S rDNA is {D78008}.

Habitat

Xenorhabdus species are insect pathogenic bacteria that occur naturally in the intestinal vesicle of nonfeeding infective stage entomopathogenic nematodes of the family Steinernematidae (Bird and Akhurst, 1983; Bovien, 1937; Poinar and Leutenegger, 1968; Fig. 11). After invading an insect host, the nematode commences development, releasing *Xenorhabdus* into the nutrient-rich hemolymph. The bacteria proliferate, killing the insect host and producing suitable nutrient conditions for nematode growth and reproduction, as well as an array of antibiotics and bacteriocins to minimize competition. As the nutrient source becomes depleted, the immature nematodes develop into dauer juveniles that will transport *Xenorhabdus* to a new nutrient source (Fig. 1; see Introduction in this Chapter).

COSPECIATION BETWEEN THE BACTERIAL SYMBIONTS AND THEIR NEMATODE HOSTS
When the taxonomic data of *Xenorhabdus* is

compared with that of their host nematodes, a close relatedness of the two taxonomic structures is noticed, and a phenomenon of cospeciation between bacterium and nematode genera is shown (Table 8). However, sometimes several species of *Steinernema* can share one species of *Xenorhabdus*. For example, symbiotic species of *S. affine*, *S. feltiae*, *S. kraussei* and *S. intermedium* share *X. bovienii* (Akhurst and Boemare, 1988; Fig. 9), although specific 16S rDNA genotypes could be recognized for each one and subspecies may be defined soon. Two species of nematodes also were reported to harbor *X. beddingii*, but unfortunately the nematode species were not described at that time (Akhurst, 1986a). A recent report describes a similar observation for the symbionts of *S. cubanum* and *S. glaseri* (Fischer-Le Saux et al., 1999a). When *S. cubanum* was described, it was considered to be a related species of *S. glaseri* because some morphological characters were very similar (Mráček et al., 1994). These morphological similarities make it difficult to distinguish the two species (Hominick

Fig. 11. *Steinernema*, nematode host of *Xenorhabdus*, and anatomical localization of the phoretic bacteria. (a) Scanning electron micrograph of dauer juveniles. Bar = 100 μ m. (b) Scanning electron micrograph of dauer juveniles. Bar = 10 μ m. (c) Scanning electron micrograph of dauer juveniles. Detail is shown of the ornamentation of the cuticle. Bar = 2 μ m. (d) Scanning electron micrograph of dauer juveniles. Bar = 1 μ m. Detail showing the closed mouth. (e) Scanning electron micrograph of dauer juveniles. Exsheathing of the old cuticle is in progress. To eliminate all the contaminants between the old and new cuticles (Fig. 11f), dauer juveniles must be removed from their old L2 cuticle during axenization. Bar = 5 μ m (from Bonifassi et al., 1999). (f) Microphotograph of native *Steinernema scapterisci* tail. Light microscopical image, using Nomarski differential interference contrast optics, shows microorganisms (arrows) between L2 and L3 cuticles before the exsheathing (arrows). Bar = 20 μ m (from Bonifassi et al., 1999). (g) Photomicrograph of the anterior part of the intestine of a dauer larva of *Steinernema feltiae* showing the vesicle containing *Xenorhabdus bovienii* symbionts. Bar = 5 μ m (from Bird and Akhurst, 1983).

et al., 1997). The restriction analysis of the intergenic transcribed spacer (ITS) of the ribosomal genes revealed high molecular similarities between *S. cubanum* and *S. glaseri* (Hominick et al., 1997), and the construction of a dendrogram illustrated their close phylogenetic relatedness (Reid and Hominick, 1998). A recent common ancestor could explain high morphological and molecular similarities between these two nematode species. The geographical isolation of the fauna from Cuba could have led to their speciation, which may be relatively recent. Although the bacterial symbionts of the two nematodes at present belong to the same species, the phenomenon of cospeciation may be in progress, and phenotypic and genotypic bacteriological discriminations are not sufficient to delineate two *Xenorhabdus* species. On the basis of these results, one can assume that the previously mentioned exceptions do not fundamentally modify the concept of a possible coevolution.

Questions similar to those asked about *Photorhabdus* (see Cospeciation in this Chapter) are: how do the bacteria and the nematodes maintain their specific association? signal compounds for recognition? specific attachment? In the case of *Xenorhabdus*, preservation of the bacterial cells from the digestion of the dauer larvae during the free-living phase of the host's life cycle is a function of the nematode's anatomy, i.e., special vesicle in the intestine of the dauer (Bird and Akhurst, 1983; Fig. 11g). This seems to be a clear coevolutionary trait, not appearing in other free-living soil-dwelling nematodes such as species of the family Rhabditida. It may be reasonable to hypothesize that specific attachment by the symbiotic bacteria to such an organ is the mechanism ensuring the maintenance of the symbiosis.

Isolation

Xenorhabdus spp. generally grow well at 25–28°C on nutrient or similar agar (e.g., Luria-Bertani, trypticase soy). Like *Photorhabdus* (see Isolation in this Chapter), *Xenorhabdus* can be isolated from the infective stage nematodes by the hanging drop technique or by maceration (Akhurst, 1980; Poinar, 1966a). For both methods the infective juveniles must first be surface sterilized; this is readily achieved by immersing a small number of live infective stage nematodes (>100), free of debris, in 0.1% merthiolate for 1 h at room temperature and then rinsing thoroughly in several changes of sterile water. In the hanging-drop technique, individual surface-sterilized infective juveniles are transferred to a drop of sterilely change by aseptically collected insect hemolymph on a cover slip that is then inverted over a cavity to prevent desiccation. The drop is incubated (1–3 d) at 25°C until the nematodes commence development. At this time, they void their symbiotic bacteria, which can be subcultured from the hemolymph onto an agar medium (e.g., nutrient agar) 1 d later. A more rapid method involves the maceration by means of a tissue homogenizer of 50–100 surface-sterilized infective juveniles in a nutrient broth. The macerated nematodes (in 10–100 µl aliquots) should be plated onto an agar medium immediately and incubated at 28°C for 3 d. The inclusion of suitable controls to confirm that the surface-sterilization procedure has been effective is essential for both methods. *Xenorhabdus* can also be isolated by the less labor-intensive method of collecting hemolymph from an insect (e.g., *G. mellonella*) larva within 24 h of its death caused by *Steinernema*. With this last method, bacteria

other than *Xenorhabdus* may also be isolated; these bacteria may be carried into the host on the exterior of the nematodes or may be picked up into the hemolymph from the insect cuticle. Contamination by other bacteria can be minimized by burying the insect in clean, damp sand, adding a small number of nematodes to the surface of the sand and incubating at 20–25°C until 1–5 nematodes infect the insect. This last method is better suited to reisolation of a *Xenorhabdus* strain rather than to identification of the bacteria specifically associated with a nematode species.

Identification

As discussed for *Photorhabdus* (see Isolation), the use of 16S rDNA probes may be useful to identify the *Xenorhabdus* species (Fig. 9). Interestingly, several PCR-RFLP 16S rRNA genotypes (Fig. 9; Table 7) can be recognized inside a DNA-DNA relatedness group that may be useful to distinguish subspecies that correlate with the nematode host species (N. Boemare, unpublished observation). This is the case of genotypes 6, 7 and 8 inside the *X. bovienii* genomic group (Brunel et al., 1997), which can be more or less related to symbionts of *S. feltiae*, *S. kraussei* and *S. affine* that are not yet distinguishable by DNA-DNA hybridizations (Figs. 9 and 10). If such an approach can be accurately verified, it will provide an amazing result since DNA-DNA hybridization is considered the gold standard method for defining species and subspecies, whereas the ribosomal methods are useful for the genera.

Xenorhabdus are easily distinguished from other Enterobacteriaceae by the absence of catalase and their inability to reduce nitrate. The key characteristics for differentiating *Xenorhabdus* from *Photorhabdus* are luminescence and

catalase. The major cellular fatty acids of *Xenorhabdus* are C_{16:0}, C_{16:1}, C_{18:1} and C_{17-cy}, and the respiratory quinone system is ubiquinone-8 (Suzuki et al., 1990). Antibiotograms scored after 3 d at 28°C show that *Xenorhabdus* are inhibited by streptomycin, neomycin, gentamycin, tetracycline, kanamycin and colistin, but not penicillin. Most strains are resistant to ampicillin and cephaloridine, and to a lesser extent, furazolidone, whereas resistance to chloramphenicol is limited. Resistance to streptomycin, tetracycline and kanamycin after selection has been demonstrated for *X. nematophila*.

Insect pathogenicity is tested by injection of 10² and 10⁴ cells (total count) from a 24-h broth culture into final instar *G. mellonella* larvae. The injected larvae should be placed on dry filter paper in Petri dishes and incubated at 25°C for 3 d. Most *Xenorhabdus* spp. will kill <50% at a dosage of 10² cells; all will kill <50% at 10⁴ cells.

Cultivation

Xenorhabdus species are easily grown in vitro on a range of complex liquid and solid media and in minimal media supplemented with nicotinic acid, *p*-aminobenzoic acid, serine, tyrosine, and/or proline (Grimont et al., 1984). Minimal medium II (BioMérieux®) contains all the necessary requirements to test utilization of organic compounds. Nutrient agar is suitable for all strains. They are mesophilic; most grow between 15 and 30°C, but strains growing at 4 or at 40°C have been isolated. All tests for phenotypic characterization of *Xenorhabdus* should be conducted at 28°C. Dye adsorption in most *Xenorhabdus* species can be tested on nutrient agar containing 0.0025% (w/v) bromthymol blue and 0.004% (w/v) triphenyltetrazolium chloride

^aThe variable region with its conserved flanking parts is only represented from positions 440 to 490 (*E. coli* numbering). Data collected from gene databases (updated April 2000) have been selected and aligned with the aid of algorithms BLAST (Altschul et al., 1997) and CLUSTAL (Thompson et al., 1997). References: (1) Liu et al., 1997; (2) Putz et al., 1990; (3) Rainey et al., 1995; (4) Suzuki et al., 1996; (5) Szallás et al., 1997.

(Figs. 12a, b). Dye adsorbing phase I colonies of *X. nematophila* will appear dark blue, of *X. bovienii* and other yellow pigmented strains tend to be green, and of *X. beddingii* are more maroon than blue because they do not adsorb so strongly; nonabsorbent phase II colonies in all of these are red (Akhurst, 1980). As *X. poinarii* does not adsorb bromthymol blue, dye adsorption in this species can be assessed on MacConkey agar; adsorbing colonies are dark red (Akhurst, 1986b; Boemare and Akhurst, 1988). Congo red (Francis et al., 1993), and some other dyes can also be used for most *Xenorhabdus* spp. Antibiotic production of phase I variants is tested by spot-inoculating *Xenorhabdus* onto nutrient agar and incubating at 28°C for 3 d. After this time the bacteria are killed by exposure to chloroform vapor for ca. 1 h. After the chloroform has evaporated from the agar, semi-solid nutrient agar (0.5%) inoculated with a suitable indicator organism (*Micrococcus luteus* or another Gram-positive species) is poured to form a thin layer. After incubation at 28°C overnight, a halo of inhibition around antibiotic-producing colonies will be evident.

Preservation

Storage in 20% glycerol at temperatures at -70°C or below is very useful for long-term maintenance of *Xenorhabdus* cultures; they do not store well at -20°C. Short-term storage (less than one month) is best conducted at 10–15°C because survival on agar or in broth at 4°C is very poor and when cultures are maintained at temperatures in excess of 15°C, the risk of a proportion of the culture undergoing phase change is significant.

A remarkable feature must be noted. Nematodes of the species *S. feltiae*, kept in collection for more than 10 years, preserve their symbionts; bacterial strains isolated after a such delay were identical, in terms of phenotypic and genotypic characters, to those initially isolated (N. Boemare and F. Grimont, personal communication). Consequently, when the conditions of storage of the nematodes are good, reisolation of the *Xenorhabdus* strain from their dauer larvae may be advised for those species where the association is strongly observed. This is not the case for the *S. glaseri* and *X. poinarii* association, which seems to be more labile.

Physiology

PHASE VARIATION Phase I *Xenorhabdus*, such as those isolated from the nematode's associates or insects infected by the nematodes, form convex, circular colonies with slightly irregular margins and a diameter of 1.5–2 mm after 4 d at 28°C;

Fig. 12. Motility and adhesion of *Xenorhabdus nematophila*. (a) Behavior of *X. nematophila* F1/1 variants on 1% NBTA agar (24-h-old colony). F1/1 cells induce a swarming colony when inoculated at the center of plates containing 0.6 to 1.2% agar. On 1% agar, periodic cycles of migration (clear zones) and cell division, also named "consolidation," (dark zones) are easily visualized (Givaudan et al., 1995). In addition adsorption of bromthymol blue on NBTA (blue colony), is a characteristic of phase I variants. (b) In contrast phase II variants show a complete lack of swarming motility (Givaudan et al., 1995), do not adsorb the bromthymol blue, but reduce the 2,3,5-triphenyltetrazolium chloride (TTC) to formazan (red colony). (c) Scanning electron micrograph of the colonization by *Xenorhabdus nematophila* strain F1 on sponge substrate coated with the nutrient medium of Wouts (1982), shows adhesion of the cells on solid substrate. Bar = 1 µm.

they also have a slightly granular appearance and, in some species, are pigmented (yellow, brown). These colonies adsorb dyes, such as bromthymol blue and neutral red, taking on intense coloration (Fig. 12a, b). Phase II variants generally form similar colonies but flatter and wider (diameter 2.5–3.5 mm after 4 d at 28°C) and with lesser pigmentation; these colonies adsorb dyes only very weakly and no coloration is evident in 4-d colonies. Phase I cells have peritrichous flagella responsible for the motility of the strain (Givaudan et al., 1995) expressed essentially in nutrient broth (Fig. 13a). Phase I, but not phase II, cells have a peritrichous array of fimbriae expressed on solid nutrient agar (Fig. 13b) with diameter of 6.4 nm, morphologically similar to the type I fimbriae of *E. coli* (Binnington and

Brooks, 1994; Brehélin et al., 1993; Moureaux et al., 1995). The glycocalyx surrounding *Xenorhabdus* cells is irregular in thickness, with a mean depth of 142 nm and 49 nm in phase I and phase II *X. nematophila*, respectively (Brehélin et al., 1993; Fig. 13c). Both fimbriae and glycocalyx are presumably responsible for the cell adhesion on substrate (Fig. 12c). Phase I cells produce during the stationary period crystalline protoplasmic inclusions characteristic of the genus (Fig. 14b, d).

With some strains of *X. nematophila*, and depending on the insect tested, phase II variants may be less pathogenic than the phase I variants. Thus an analysis of pathogenicity in *Manduca sexta* larvae revealed that the phase II variant of AN6 was significantly less virulent than the phase I variant (Völgyi et al., 1998). The phase II variant of *X. nematophila* strain N2-4 was also avirulent for *M. sexta*. On the other hand, F1/II and 19061/II were as virulent as their respective phase I cells. Consequently phase traits of *Xenorhabdus*, which are mainly involved in the growth and development of nematodes, may be considered as “symbiotic characters,” and to some extent depending on the biotic conditions of the infection (infecting strain and susceptibility of the insect), more or less linked with virulence factors. Nevertheless the role of phase II remains uncertain in *Xenorhabdus*, as in *Photorhabdus*.

Fig. 13. Surface appendages of *Xenorhabdus nematophila* phase I variants. (a) Transmission electron micrograph of F1/1 cell from nutrient broth culture, showing peritrichous flagella; negative staining with 1% phosphotungstate. Bar = 0.5 μ m. (b) Transmission electron micrograph of F1/1 cells from nutrient agar at 1.5% previously dried to minimize expression of flagella, showing fimbriae (or pili) around the cell wall. Bacteria were fixed 1.25% glutaraldehyde and 1% paraformaldehyde in 0.015M sodium cacodylate buffer (pH 7.4; 10 min) and were negatively stained with 0.5% phosphotungstate (from Moureaux et al., 1995). Bar = 0.25 μ m. (c) Transmission electron micrograph of A24/1 cell grown on nutrient agar. Cell fixed with glutaraldehyde-lysine-osmium tetroxide and stained with ruthenium red, uranyl acetate and lead citrate shows significant glycocalyx surrounding the cell wall (arrows). Bar = 0.5 μ m (from Brehélin et al., 1993).

SWARMER CELLS Givaudan et al. (1995) demonstrated that *Xenorhabdus* phase I variants displayed a swarming motility when they were grown on a suitable solid medium (0.6–1.2% agar; Fig. 12a, b). Unlike most phase I variants of different *Xenorhabdus* spp., phase II variants were unable to undergo cycles of rapid and coordinated population migration (swarm and even to swim) over the surface of semisolid agar, particularly those of *X. nematophila*. Optical and electron microscopic observations showed that the nonmotile phase II cells of *X. nematophila* F1 lacked flagella. When flagella from strain F1 phase I variants (Fig. 13a) were purified, the molecular mass of the flagellar structural subunit was estimated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis to be 36.5 kDa. Flagellin from cellular extracts or culture medium of phase II cells was undetectable with antiserum against the denatured flagellin by immunoblotting analysis. This suggests that the lack of flagella in phase II cells is due to a defect during flagellin synthesis as has been demonstrated by genetic studies. (See Genetics in this Chapter)

PRODUCTION OF SECONDARY METABOLITES As for *Photorhabdus*, phase I variants of *Xenorhabdus*

Fig. 14. Ultrastructural traits of *Xenorhabdus nematophila* cells. (a) Freeze-etching of strain F1 cell showing the outer (om) and the inner (im) membranes of the cell wall. Cleavage faces have been displayed, both at the level of cell wall and of plasma membrane. Glutaraldehyde (2.5%) in 0.1 M cacodylate buffer (pH 7.2) was added at 37°C for 1 h. The flask was rinsed with the cacodylate buffer at laboratory temperature, and the cells were gently scraped. The cells were sedimented by low-speed centrifugation, and the pellet was impregnated with 25% glycerol for 20 to 30 min to avoid ice-crystal formation. These samples were again centrifuged, and then were sandwiched between two specimen-holder dishes 3 mm in diameter, in preparation for the double-replica technique. They have been fractured in a Cryofract and both complementary fractures were shadowed by platinum evaporation. The replicas were cleaned in sodium hypochloride, rinsed in double distilled water, dried, and examined in a transmission electron microscope. Bar = 0.4 μ m. (b) Cultures of 5-d stationary growth of strain F1 fixed with 2.5% glutaraldehyde and 1% osmium tetroxide, and stained with uranyl acetate and lead citrate. Crystalline inclusions (arrows) begin by a condensation of amorphous material (am), which crystallizes as rhomboedric bodies. Bar = 0.8 μ m. (c) Same as b, except bar = 0.1 μ m. (d) Same as c but shows details of the crystallization of the inclusion. Bar = 0.1 μ m.

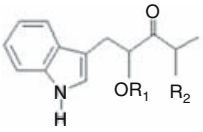

produce a variety of secondary metabolites, some of which have antimicrobial properties (Akhurst, 1982a; Table 10). Four chemical groups have been characterized: indole derivatives (Li et al., 1996; Li et al., 1997; Paul et al., 1981; Sundar and Chang, 1993; Webster et al., 1996), xenorhabdins (McInerney et al., 1991a; Rhodes et al., 1987), xenorxides (oxidized xenorhabdins) and xenocoumacins (Gregson and McInerney, 1989; McInerney et al., 1991b). Maxwell et al. (1994) examined occurrence of the xenocoumacins in vivo (in the insect *Galleria mellonella*) and in vitro (in tryptic soy broth). The level of antibiotic activity was greater under in vivo than in vitro conditions. These experi-

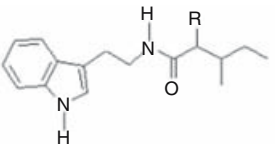

ments demonstrate that *Xenorhabdus* antibiotics may play an important role by preventing microbial contamination in the insect carcass during the development of nematodes. The production of antimicrobials provides at least a partial explanation for the “natural monoxeny” during parasitism.

LYSOGENY AND BACTERIOCINOGENY The presence of lysogenic phage in and production of bacteriocins by *X. nematophila* was demonstrated by Boemare et al. (Boemare et al., 1992; Fig. 15). Lysis of either phase of *X. nematophila*, *X. bovienii* or *X. beddingii* in response to mitomycin C or heat shock released complete and partial

(e) Detail of a complete phage of strain A24. Bar = 50 nm. (f) Detail of an A24 phage with empty head. Bar = 50 nm (from Boemare et al., 1992; Baghdiguian et al., 1993; Thaler et al., 1995).

phages. The phage of *X. nematophila* belongs to the family Siphoviridae, as does the λ phage from *E. coli*. The phage head capsid has one major and two minor subunits (Thaler et al., 1995).

The bacteriocins are phage tail-like particles, which in addition to inhibiting non-host *Xenorhabdus*, inhibited *P. luminescens*, *Proteus vulgaris* and *Morganella morganii*. However, none of the other Gram-negative or Gram-positive bacteria tested were inhibited, indicating that the bacteriocins act against closely related genera, in contrast to the antibiotics produced by phase I variants that have a wide spectrum of activity (Boemare et al., 1992; Table 11). Electron microscopic studies of the *X. nematophila* bacteriocin, named xenorhabdycin (Thaler et al., 1995), show that bacteriocin particles have the structure of a rigid phage tail without any "head" (Baghdiguian et al., 1993; Fig. 15). Biochemically, xenorhabdycin was shown to consist of two major protein bands, corresponding to the sheath and core, and five minor bands (Thaler et al., 1995).

The inhibition by several dilutions of a xenorhabdycin suspension was scored 24 h after deposit on a lawn of the bacterial target (+, clear zone at the droplet site, -, no clear zone). The bacteriocin suspension was purified from a culture of *X. nematophila* A24 ($A_{600} = 0.5$) after induction by mitomycin C or heat shock and was diluted up to 10^{-5} (Thaler et al., 1995) before assessing bacteriocin activity. When noninduced cultures were centrifuged and the filter-sterilized supernatants were tested similarly, a residual bacteriocin activity was noted for the same susceptible target strains of this table, meaning that a spontaneous bacteriocinogenesis occurs in untreated cultures, albeit at a lower frequency than in induced cultures (Boemare et al., 1992). The xenorhabdycin producer strain and strains belonging to the same species are immune from this antibiotic activity (blue box in the table), strains of other species of *Xenorhabdus* and *Photorhabdus* are susceptible (red box), and the only other genera containing susceptible strains are *Proteus* and *Morganella* (pink box), showing that

this bacteriocin is active only against species closely related to *X. nematophila*.

Genetics

Genetic studies (comprehensively reviewed by Forst and Neilson, 1997; Forst et al., 1996) have been undertaken to analyze the mechanisms and functions of pathogenicity, symbiosis and phase variation. Couche et al. (1987b) demonstrated the presence of one or two small plasmids (3.6–12 kb) in some, but not all, *X. nematophila* and *X. bovienii* strains. The plasmid profiles did not differ between phases I and II. Smigielski and Akhurst (1994a) reported two megaplasmids (71.8 and 118.5 kb) as well as two additional plasmids (6.5 and 17 kb) in the A24 strain of *X. nematophila*. They also demonstrated that all strains of *X. nematophila*, *X. bovienii*, *X. beddingii* and *X. poinarii* contained megaplasmids (48–680 kb) and that the megaplasmid profiles of phases I and II were not different. Small or large plasmids of *Xenorhabdus* have not been further characterized or engineered to generate cloning vectors.

Conjugation of plasmids from *E. coli* has been applied successfully for *X. nematophila* and *X. bovienii* (Forst and Neilson, 1996; Francis et al.,

Table 12. Identified genes and proteins from *Xenorhabdus* strains.

References (1) Forst et al., 1995; (2) Givaudan et al., 1996; (3) Givaudan and Lanois, 2000; (4) Tabatabai and Forst, 1995; (5) Völgyi et al., 2000

1993; Givaudan and Lanois, 2000; Givaudan et al., 1996; Völgyi et al., 2000). In contrast, transformation of *Xenorhabdus* has not been generally successful. Although Xu et al. (1989) reported the transformation of the type strain of *X. nematophila* with a broad host-range vector, they and other workers have been unsuccessful with other strains of *X. nematophila* and other *Xenorhabdus* spp. The increase in transformation efficiency after the vector had been passaged through *X. nematophila* suggested the presence of a restriction modification system. Endonuclease activities have been detected in a range of *Xenorhabdus* spp. and it appeared that their DNA was strongly methylated (Akhurst et al., 1992). *Xenorhabdus bovienii* wild-type strains lack a functional receptor protein (LamB) in the outer membrane and as a result are unable to adsorb the phage λ of *E. coli*. Francis et al. (1993) developed a transposon mutagenesis system for *X. bovienii* by constitutively expressing the LamB protein on the surface of the bacterium allowing them to be infected with λ particles carrying the Tn10 transposon. This process produced various dye-binding, lipase, protease, hemolytic, DNase and auxotrophic mutants, i.e., alteration of phase and virulence traits. Unfortunately, use of such material for analysis of phase variation was not further continued (see Genetics/Regulation of Phase Variation in this Chapter). The Tn5 transposon was used to induce a low frequency of mutagenesis in *X. nematophila* (Xu et al., 1991) and the mini-Tn10 transposon carried on pLOF-Km^r has been introduced into *X. nematophila* by conjugal transfer (Völgyi et al., 2000).

GENES AND PROTEINS Several genes have been identified in *Xenorhabdus* strains (Table 12). Regulation of outer membrane protein (Opns) genes of *X. nematophila* was shown in response to growth period and growth temperature (Forst

et al., 1995; Leisman et al., 1995). In *E. coli*, the OmpR and OmpC proteins form pores that allow diffusion across the outer membrane. The genes encoding them are regulated by several environmental stimuli. This is mediated by a two-component regulatory system: an EnvZ sensor protein, activated by environmental changes to phosphorylate the OmpR regulatory protein, and the *ompF* and *ompC* genes, regulated by OmpR regulatory protein. The *ompR* and *envZ* two-component signal transduction genes of *X. nematophila* were shown to constitute a single operon regulated by a σ^{70} promoter. One function of EnvZ in *X. nematophila* is to regulate the expression of OmpRs during the stationary period of growth.

Phase I variants of *X. nematophila* strain F1 were motile (see Physiology—swarming in this Chapter), whereas phase II variants were non-flagellated cells that did not synthesize flagellin (Givaudan et al., 1995). A locus containing two open reading frames (ORFs) was identified from phase I cells by using functional complementation of flagellin-negative *E. coli* (Givaudan et al., 1996). The sequence analysis revealed that the first ORF corresponds to the *fliC* coding for flagellin, and showed a high degree of homology between the N-terminal and C-terminal of *Xenorhabdus* FliC and flagellins from other bacteria. The second ORF, which is in the opposite orientation, encodes a homologue of the enterobacterial hook-associated protein 2, FliD. Both the *fliC* and *fliD* genes of *Xenorhabdus* were required for the complete restoration of *E. coli* motility. A sequence highly homologous to the σ^{28} -consensus promoter was identified upstream from the coding sequences of both genes. The structure of the *fliC* gene and its surrounding region was shown to be the same in both phase variants, but Northern blot analysis revealed that *fliC* and *fliD* were, respectively, not and weakly transcribed in phase II variants. The loci, the transcriptional activators of flagellar genes, *flhDC*, were identified (Givaudan and Lanois, 2000).

REGULATION OF PHASE VARIATION AND VIRULENCE FACTORS Hypovirulent and avirulent mutants have been produced in *X. nematophila* by chemical and transposon mutagenesis (Dunphy, 1994; Xu et al., 1991). *N*- β -hydroxybutanoyl homoserine lactone (HBHL), the autoinducer of the luminous system of *Vibrio harveyi*, restored virulence to previously avirulent mutants (Dunphy et al., 1997) by increasing lipase activity and lowering phenol oxidase activity in the hemolymph of insects infected with the wild strain, parameters that are associated during pathogenesis. When avirulent mutants are injected, lethality for the insect is restored upon

injection with HBHL. Because HBHL, or a closely related analogue, is excreted by the wild-type *X. nematophila*, a role for an HBHL-dependent regulatory system in its virulence process is indicated. The luminescence and virulence of *V. harveyi* against prawns (associated with a toxic extracellular protein) have been suggested to be coregulated under the control of an intercellular quorum-sensing mechanism involving the HBHL and another uncharacterized signaling molecule (Manefield et al., 2000).

Three phenotypically similar variants of *X. nematophila* strain AN6, each containing a single transposon insertion, were obtained by transposon mutagenesis (Völgyi et al., 2000). The insertions occurred at different locations in the chromosome. The variant ANV2 (AN6/1::Tn10 Amp^r Km^r) neither produced antibiotics nor the outer membrane protein OmpB, but produced lecithinase. The transposon had inserted in a novel gene designated *var1*, which encodes a protein of 121 amino acid residues. Complementation analysis confirmed that the pleiotropic phenotype of ANV2 was produced by inactivation of *var1*. However this *var1* gene does not complement any other phase II variants. These results indicate that inactivation of a single gene can affect multiple phase traits. More generally, all the experiments inactivating some specific phase traits by mutations or overexpression of a structural gene affect one or few functions, but none has been found to affect all the phase-related functions.

Complementation experiments showed that motility and flagellin synthesis of phase II cells cannot be recovered by placing in *trans* the *fliCD* operon from phase I cells (Givaudan et al., 1996). A gene(s) higher in the transcriptional hierarchy of the flagellar regulon, acting in *Xenorhabdus* phase II variants, was investigated. Givaudan and Lanois (2000) constructed *X. nematophila* *flhD* null mutants showing that *flhDC* operon controlled flagellin expression. But at the same time this experiment showed that lipolytic and extracellular hemolysin activities also were altered. In addition, the *flhD* null mutant displayed a slightly attenuated virulence phenotype in the insect *Spodoptera littoralis*. Thus, these data indicate that the phenotypic phase traits of *X. nematophila* (such as motility, lipase, hemolysin) participated also in the infectious process in insects. On the other hand, even if the flagellar regulon is considered to be one of the master genes involved in some aspects of phase variation, a super-regulator that controls the total phase mechanism has not been discovered. Nevertheless we should note that, in contrast with *Photorhabdus*, phase variation in *Xenorhabdus* is regulated transcriptionally.

All the analyses to date have shown that different phase variant characteristics are separately controlled. However, it seems unlikely that phase variant phenotypes are all controlled independently of each other. It is probable that a master switch differentially affects a number of other regulatory systems that in turn control one or a small number of phase variant characteristics. In no case has a common regulator (controlling the whole phenomenon) been identified.

Ecology

Xenorhabdus species have been found only in the intestinal tract of infective stage nematodes of the genus *Steinernema* (syn. *Neoaplectana*) and in insects killed by these nematodes. There is a high degree of specificity in these associations, with each nematode species being naturally associated with only one *Xenorhabdus* species. This specificity is determined by the ability of the nematode to retain the bacterium in its intestinal vesicle (Akhurst and Boemare, 1990; Bird and Akhurst, 1983). Although other bacteria in association with *Steinernema* have been reported (Aguillera et al., 1993; Lysenko and Weiser, 1974), closer examinations have always demonstrated that only *Xenorhabdus* have a specific association (Akhurst, 1982b; Bonifassi et al., 1999). For example, gnotobiology of *Steinernema scapterisci* and bacteriological study of its symbiont, confirmed that this nematode harbors a symbiotic species of *Xenorhabdus*, as do other *Steinernema* species. Bacteria, reported previously as associating with this nematode and belonging to several other genera, are contaminants located in the intercuticular space of the infective juveniles (Bonifassi et al., 1999). These bacteria were detrimental to nematode reproduction in *Galleria mellonella*. Combination of the symbiont and its axenic host gave the best yields of infective juveniles (IJs) when produced in this insect and in vitro production on artificial diet.

The infective stage nematodes act as vectors, transporting the bacteria into the insect via natural orifices (mouth, anus and spiracles) and then into the hemocoel (Fig. 2; see *Photorhabdus* and *Xenorhabdus* in this Chapter). The infective (dauer) nematode, a third-stage juvenile with closed mouth and anus, recommences development in the hemocoel, releasing its symbiotic bacterium and an inhibitor of the inducible antibacterial enzymes (Götz et al., 1981; Poinar and Himsworth, 1967a). As *Xenorhabdus* multiplies, it provides essential nutrients for nematode maturation and reproduction (Poinar and Thomas, 1966b) and antibiotics (Akhurst, 1982a; Li et al., 1996; Li et al., 1997; McInerney et al., 1991a; Paul et al., 1981).

Xenorhabdus alternate between a nutrient-rich (insect) and nutrient-poor (nematode) existence. Forst and Neilson (1996) hypothesized that phase II may be induced by the nematode gut conditions and better adapted to the nutrient-poor conditions of the intestinal vesicle of the nonfeeding nematode. However, this hypothesis does not account for the fact that the bacteria isolated from field-collected infective stage juveniles are inevitably phase I cells. Smigielski et al. (1994b) found differences in the activity of respiratory enzymes of both phase I and II cells that indicate the greater potential of phase II forms to survive in soil environments than phase I. The lack of a record of isolation of *Xenorhabdus* directly from soil may be due to its slow growth, lack of a suitable selective medium, and/or the difficulty of identifying phase II cells, which has few positive characters in most standard tests for identifying bacteria. However, Morgan et al. (1997) found that *X. nematophilus* declined very quickly in river water and soil, becoming undetectable after 2 d and 7 d, respectively. At this time, there is no satisfactory explanation of the ecological role of phase II forms.

Steinernematidae living in the soil, but specialized as insect parasites, belong to a large group of nematodes in the order Rhabditida that feed on various microorganisms. The Steinernematidae, although adapted to a particular symbiotic bacterium, have retained the ancestral microbivorous behavior allowing them to feed and reproduce on microorganisms other than their own symbiont. In spite of this feeding behavior, however, it has been shown by several researchers that bacteria other than the symbiont are not as favorable as the symbiont for growth and reproduction of *Steinernema* (Akhurst, 1982c; Boemare, 1983a; Ehlers et al., 1990), and not efficient enough to allow the perenniality of a symbiotic association (Akhurst and Boemare, 1990).

Further microbial ecological studies are needed to explain the durability over many generations of the *Xenorhabdus*–*Steinernema* intestinal symbiotic associations. The concept of the occurrence of a natural monoxeny in these bacterium–helminthic symbioses (Bonifassi et al., 1999) must be accepted, if we consider the following features. In natural conditions, if any bacterial co-associate is carried in the IJs, perhaps the IJs and associated bacteria could kill insects, but the probability of the nematode reproducing inside the insects and providing viable IJs is low. Consequently, the chances of an ecologist isolating polyxenic parasitized insects from the soil are very small due to the scarcity of these occurrences and to the short period of time between infection of an insect and its putrefaction, which would destroy any traces of the association.

Disease

No effects on vertebrates have been demonstrated (Obendorf et al., 1983; Poinar and Thomas, 1967b; Poinar et al., 1982).

Xenorhabdus is an insect pathogen only when delivered into the insect hemocoel, either by their nematode symbiont or by injection; they are not pathogenic when applied per os or topically. Most are highly pathogenic for larvae of the greater wax moth, *Galleria mellonella*, with LD₅₀s of less than 20 cells (Akhurst and Dunphy, 1993). *Xenorhabdus poinarii* has very little pathogenicity for *G. mellonella*, (LD₅₀ = 5,000 cells) when injected alone, although it is highly pathogenic when co-injected with axenic *Steinernema glaseri*, its natural host (Akhurst, 1986b). Axenic *S. scapterisci* and its symbiont *Xenorhabdus* strain UY61 alone are also not pathogenic to *G. mellonella*. The combination of both partners re-established the pathogenicity of the complex towards *G. mellonella* (Bonifassi et al., 1999). Pathogenicity of *Xenorhabdus* varies between insects, with *X. nematophila* having an LC₅₀ of about 500 for *Hyalophora cecropia* caterpillars, and no effect on maggots of the genus *Chironomus* (Götz et al., 1981). The use of a less susceptible host (e.g., *Manduca sexta*) has enabled detection of differences in pathogenicity between the two phases of a strain (Völgyi et al., 1998).

Applications

Knowledge about the nutritional requirements provided by the symbionts would improve the industrial mass production of the entomopathogenic nematodes for biological control of insect pests. Similar comments made about *Photorhabdus* (see *Photorhabdus*/Applications in this Chapter) can be applied to *Xenorhabdus*.

Some of the secondary metabolites have commercial potential in the pharmaceutical and agro-forestry industries (Webster et al., 1998). Among the isolates examined to date from *X. nematophila* and *X. bovienii*, some indole, xenocoumarin and xenorhabdin derivatives are antibacterial, and/or antifungal, especially when they are cultivated in vitro. This is of great interest to industry (Table 10).

Moreover, the occurrence of protein toxins identified in some *Xenorhabdus* strains has enhanced interest in the bacteria alone for biological control applications. As with *Photorhabdus* (see *Photorhabdus*/Applications), programs to insert toxin genes into plant genomes for crop protection have been proposed. Today four patents have been submitted for such exploitation (East et al., 1999; Jarrett et al., 1997; Kramer et al., 1999a; and Smigielski and Akhurst, 1995).

The Family Vibrionaceae

J. J. FARMER III

The family Vibrionaceae contains a variety of very important organisms (Table 1). The type genus for the family is *Vibrio* and the type species is *Vibrio cholerae*, an organism that has killed millions of people during numerous devastating epidemics of cholera that terrorized most parts of the world. The family Vibrionaceae includes several species that cause intestinal tract and extraintestinal infections in both humans and animals. Many of the species of Vibrionaceae are widely distributed in the environment, where they contribute to the cycling of organic and inorganic compounds. Species of Vibrionaceae have also been widely used in physiological, biochemical, molecular biology, and pathogenicity studies (Baumann and Baumann, 1981; Baumann and Schubert, 1984; Hastings and Nealson, 1981). There are many literature citations for some of the species, but only a few for others (Table 1).

History, Nomenclature, and Classification

Formation of the Family in 1965

In the seventh edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957), the vibrios and related fermentative bacteria were split into a number of families (Table 2). The name Vibrionaceae was formally proposed in 1965 by Véron (Véron, 1965) as a convenient grouping for fermentative bacteria that have polar flagella and a positive oxidase reaction. One year previously, Eddy and Carpenter (1964) had also noted the similarities of *Aeromonas*, *Plesiomonas*, and *Vibrio* and thought they should not be split between the families Pseudomonadaceae and Spirillaceae (Table 2). They stated, “the creations of a new family, possibly named Vibrionaceae, might well be justified for these organisms.” This was a suggestion rather than a formal proposal, thus the name “Vibrionaceae (Eddy and Carpenter 1964)” had no standing in nomenclature. However the name Vibrionaceae was formally proposed a year later and “Vibrionaceae (Véron 1965)” does have standing in nomenclature. This classification

allowed the clear differentiation of Vibrionaceae from the closely related family Enterobacteriaceae, whose members differ in being oxidase negative and having peritrichous flagella (Table 3). Until the proposal by Véron, the genera and species of Vibrionaceae were scattered among a number of different bacterial orders and families (Table 2) (Breed et al., 1957). In this and many other early classifications, cellular morphology was of prime importance in assigning species to genera and families (Buchanan et al., 1966; Buchanan and Gibbons 1974; Campbell, 1957; Gibson et al., 1977; Hendrie et al., 1970; Shewan et al., 1960; Subcommittee, 1966, 1972). Organisms with a curved shape were often classified together as “vibrios” or “*Vibrio* species,” regardless of their other properties. This allowed anaerobic vibrios such as *Vibrio succinogenes*, microaerophilic vibrios such as *V. fetus*, and non-fermentative vibrios such as *V. psychroerythrus* to be included in the genus *Vibrio*, merely because they all had curved shapes. These and many others have now been removed from the family. Another problem with early classifications was the undue importance attached to the arrangement of flagella. Polarly flagellated and peritrichously flagellated organisms were usually placed in separate families (Table 2). It is now known that many species of Vibrionaceae have polar flagella when grown in liquid media, but synthesize peritrichous flagella when grown on solid media (Baumann and Baumann, 1981; Baumann and Schubert, 1984). For all these reasons, organisms now classified in the family Vibrionaceae were classified in different families in 1957 (Breed et al., 1957). The proposal of Véron in 1965 was very important because for the first time it brought together organisms that shared many phenotypic properties. The family name Vibrionaceae has been widely used and accepted for over 20 years (Baumann and Baumann, 1981; Baumann and Schubert, 1984; Farmer et al., 1985; Gibson et al., 1977; Hendrie et al., 1970), and there is a Subcommittee of the International Committee of Systematic Bacteriology that deals specifically with the family Vibrionaceae (Subcommittee, 1966, 1972, 1975, 1986). Table 1 gives the classification of Vibrionaceae used in this and the following two chapters and the number of literature citations found for

This chapter was taken unchanged from the second edition.

^aCitations in *Medline* from its beginning in 1966 through December 31, 1989, and in *Biosis* from its beginning in 1969 through December 31, 1989. The search was made by using both the "genus + species name" (example—*Aeromonas media*) and the "abbreviated genus name + species name" (example—*A. media*). Occasionally, this latter name resulted in erroneous citations because some species names also occur in other genera, a few of which also shared the first letter of the genus name. We have tried to remove these before making the final tabulations.

^bThese include strains that appear to belong in the family but lack a genus and a species name.

each genus and species. More complete information on these genera and species is given in the following two chapters.

Classification Based on Comparisons of Nucleic Acids and Proteins

In the past, bacterial classifications were based primarily on morphological and physiological

Genus VIII. <i>Proteus</i>	—
Genus IX. <i>Salmonella</i>	—
Genus X. <i>Shigella</i>	—

^aThe genera shown as “+?” probably included at least some strains that today would be considered as members of Vibrionaceae (see text).

characteristics (Breed et al., 1957; Buchanan et al., 1966; Buchanan and Gibbons, 1974). More recently, studies have focused on the structure, regulation, or function of proteins (Bang et al., 1978; reference is not an exact match Baumann et al., 1980; Baumann and Baumann, 1973, 1978; Chludzinski et al., 1972; Cocks and Wilson, 1972; Cohen et al., 1969; Crawford, 1975; Harris and Steinman, 1977; Jensen and Rebello, 1970) and nucleic acids (Anderson and Ordal, 1972; Baumann and Baumann, 1976; Brenner et al. 1983; Gibson et al., 1979; Hori and Osawa, 1979), and have given a much better picture of the evolutionary history of Vibrionaceae and their possible origin and phylogeny.

GUANINE PLUS CYTOSINE (GC) RATIO One of the first techniques used to compare organisms in the family was the GC content of the DNA.

Fig. 1. The GC content of the DNA of the genera of Vibrionaceae and of the family Enterobacteriaceae.

Table 3. Characteristics of the families Enterobacteriaceae, Vibrionaceae, and Pseudomonadaceae.

Characteristic ^a	Property of family ^b		
	Enterobacteriaceae	Vibrionaceae	Pseudomonadaceae
Typical genus	<i>Escherichia</i>	<i>Vibrio</i>	<i>Pseudomonas</i>
Metabolism of D-glucose	Fermentation	Fermentation	Oxidation
Cellular morphology			
Straight rods	+ ^a	(–)	+
Curved rods	–	(+)	–
Flagella location	Peritrichous	Polar ^c	Polar
Grow in the presence of oxygen	+	+	+
Grow in the absence of oxygen	+	+	–
Oxidase test	–	+	+
Bioluminescent	–	v	–
Na ⁺ required for growth	–	(+)	–
Inhibited by the vibriostatic compound 0129	–	+	–

^aThese characteristics are typical of the genera and species in each family, but there are some exceptions.

^bSymbols: +, most species positive; (+), many species positive; v, species-to-species variation, some species positive; (–), many species negative; –, most species negative.

^cSome species of *Vibrio* have a sheathed polar flagellum when grown in a liquid medium, but have peritrichous flagella when grown on a solid medium.

Figure 1 compares the GC content of the four genera of Vibrionaceae. The range of GC content is 38–60%, which is similar to the values found in the family Enterobacteriaceae. In the family Vibrionaceae, *Vibrio* and *Photobacterium* have a low GC content while *Aeromonas* has a high GC content.

DNA-DNA HYBRIDIZATION STUDIES These studies have been very helpful in defining the species in the family, and for showing that some of these species are more closely related to each other than to other organisms (Anderson and Ordal, 1972; Baumann and Baumann, 1976; Brenner et al., 1983). For example, *Vibrio cholerae* is closely related to *V. mimicus* by this technique (see The Genera *Vibrio* and *Photobacterium* in this Volume) and these two species might comprise a redefined genus *Vibrio* in a phylogenetic classification. This technique has also been used to show that *Plesiomonas shigelloides* and *Aeromonas* do not have any close relatives in *Vibrio*, *Photobacterium*, or among the species of Enterobacteriaceae (Brenner et al., 1983).

RIBOSOMAL RNA-DNA HYBRIDIZATION; rRNA CATALOGS AND SEQUENCES These recent studies have better defined the relationship of organisms in the families Vibrionaceae, Enterobacteriaceae, and Pasteurellaceae. The rRNA-DNA homology studies of Baumann and Baumann (1976, 1981) and the analysis of 5s rRNA catalogs of Fox et al. 1980 were based on a limited number of species (Fig. 2), but indicate that *Vibrio* and *Photobacterium* are closely related (Figs. 2 and 3). Similarly, four genera in the fam-

Fig. 2. Relationships of Vibrionaceae, Enterobacteriaceae, and related organisms based on rRNA-DNA hybridization. (Redrawn from the data of Baumann and Baumann, 1981; and Fox et al., 1980.)

ily Enterobacteriaceae—*Escherichia*, *Enterobacter*, *Serratia* and *Proteus*—are closely related to each other, but not as closely related to the Vibrionaceae. *Aeromonas* and *Pasteurella multocida* occupy a position between *Vibrio*–*Photobacterium* and Enterobacteriaceae, but are closer to the latter. *Plesiomonas* appears to occupy a position between the families Enterobacteriaceae and Vibrionaceae.

STRUCTURE, FUNCTION AND REGULATION OF PROTEINS In addition to the data from nucleic acids, there are several studies that compared the regulation and activity of enzymes in different species. Enzymes from different cultures are isolated and purified and then studied in greater detail. For example, Enterobacteriaceae and Vibrionaceae have similar pathways for the synthesis of amino acids that belong to the “aspartic acid family” (Baumann and Baumann, 1973, 1981; Cohen et al., 1969). Species in both families have three isofunctional aspartokinases. One of these enzymes is feedback inhibited by the L-threonine, but the second is inhibited by L-lysine, and the third is not inhibited by L-threonine, L-lysine, or any of the aspartic acid family of amino acids (Baumann and Baumann, 1973). This pattern is different for many other bacterial families, so these data are consistent with a common evolutionary origin for Enterobacteriaceae and Vibrionaceae (Fig. 3). Similar data from studies of 3-deoxy-D-arabinoheptulose-7-phosphate synthetase (Chludzinski et al., 1972; Bang et al., 1978; Jensen and Rebello, 1970) and of enzymes of the tryptophan biosyn-

Fig. 3. Possible evolutionary pathway of the families Enterobacteriaceae, Vibrionaceae, and other members of the purple bacteria (proteobacteria) based on 16S rRNA sequence data. The two-digit numbers at the branching points are S_{AB} values, which are derived from mathematical analysis of the catalogs of oligonucleotide sequences and indicate the degree of relatedness. Redrawn from the data in Figure 4 of Fox et al., 1980.

thetic pathway (Bieger, 1978; Crawford, 1975) also give similar results. One of the few studies that has included *Plesiomonas* was by Baumann et al. (Baumann and Baumann, 1978; Baumann et al., 1980a), who compared the structure of the enzyme glutamine synthetase by microcomponent fixation. They concluded that *Plesiomonas shigelloides* was slightly more closely related to *Escherichia coli* than to *Vibrio*. This was an interesting finding since *P. shigelloides* also contains the enterobacterial common antigen (Whang et al., 1972).

Origin and Evolution of the Family Vibrionaceae

Evidence from the primary sequence of 16S rRNA suggests that there were three major evolutionary lines in the development of life on earth, and these have been proposed as the three primary kingdoms (see Chapter 1 and Woese, 1985). All of the organisms included in the family Vibrionaceae belong to the eubacterial kingdom and to the "purple bacteria" branch of this kingdom (Woese, 1985) (Fig. 3). The purple bacteria (proteobacteria) are a diverse group that includes heterotrophic bacteria that are both fermenters and nonfermenters (Fig. 3). It also includes photosynthetic bacteria (*Chromatium*) and sulfate-reducing bacteria (*Desulfovibrio*). These data generally agree with the relatedness of the various genera, as determined by rRNA-DNA hybridization (Fig. 2).

Removal of the Genus *Aeromonas* from the Family Vibrionaceae

Colwell et al. (1986) proposed removing the genus *Aeromonas* from the family Vibrionaceae and classifying it in a new family Aeromonadaceae as the only genus. Previous authors (Baumann and Schubert, 1984) had also commented on the divergence of *Aeromonas* from *Vibrio-Photobacterium*, which is easily visualized by the differences in the GC content of their DNA (Fig. 1). A number of studies have indicated that there is considerable divergence among the genera of Vibrionaceae and of other bacterial genera and families. However, the best way to indicate this divergence is still a controversial question. The classifications of plants, animals, and bacteria above the level of genus have been controversial and subject to numerous changes and instability with time (Mahr, 1982; Ross, 1974).

Removal of the Genus *Plesiomonas* from the Family Vibrionaceae

MacDonell and Colwell (1985) proposed the removal of *Plesiomonas shigelloides* from the

family Vibrionaceae and its classification in the genus *Proteus* as *Proteus shigelloides*. This was based on sequence data of 5S rRNA. Other investigators had previously classified this organism in *Aeromonas* (Ewing et al., 1961) or *Vibrio* (Hendrie et al., 1971). The best place for *Plesiomonas* at a level above genus is uncertain, but all of the existing data except that of MacDonell and Colwell (1985) indicate that *Plesiomonas* is a separate well-defined genus.

Clearly, more data for all species in these families are needed, as are better definitions for the taxonomic ranks above genus (Stackebrandt et al., 1988; Wayne et al., 1987). Until these data become available and have been confirmed in several laboratories, it seems prudent to take a conservative approach and keep *Aeromonas* and *Plesiomonas* in the family Vibrionaceae because this classification has been universally accepted for many years. For those who wish to maintain this traditional classification, but still recognize the divergence of *Aeromonas*, it would be logical to reduce the family Aeromonadaceae to the level of subfamily where it would become "Aeromonadoideae subfamily nova." The type genus for this subfamily would be *Aeromonas*, and its description would be the same as for the family Aeromonadaceae. This proposal would automatically create "Vibrionoideae, subfamily nova," which would become the type subfamily of family Vibrionaceae. The type genus of the new subfamily Vibrionoideae would be *Vibrio*, and its description would be the same as that given by Baumann et al. (1985). Formal proposal to give these names standing in nomenclature will be made.

Similarities and Differences Among the Genera of Vibrionaceae

As previously stated, the family Vibrionaceae was originally defined by Véron (1965) to include bacteria with the following properties: grow well on ordinary peptone media, and usually grow on media with bile salts, such as MacConkey agar; oxidase positive; motile with polar flagella. There are other similarities, but these have been the main defining characteristics of the family (Table 3). Table 4 lists the most important characteristics that differentiate the four genera in the family and that differentiate species of Vibrionaceae from species in other families. However, with the discovery of many new genera and species, it is becoming increasingly difficult to write descriptions of higher taxa such as genera and families (Stackebrandt et al., 1988; Wayne et al., 1987).

Table 4. Properties of the four genera in the family Vibrionaceae.^a

Test ^b or property	<i>Vibrio</i>	<i>Photobacterium</i>	<i>Aeromonas</i>	<i>Plesiomonas</i>
Cause human infections	+	—	+	+
GC content of DNA (mol%)	38–51	40–44	57–63	51
Sheathed polar flagellum	+	—	—	—
Accumulate poly- β -hydroxybutyrate, but do not utilize β -hydroxybutyrate	—	+		
Na ⁺ required for (or stimulates) growth	+	+	—	—
Sensitive to the vibriostatic compound 0129	+	+	—	+
Lipase production	+	V	+	—
D-Mannitol fermentation	+	—	+	—

^aThese are properties of most species in the genus, but there are exceptions. Adapted from Baumann and Schubert (1984).

^bSymbols: +, most strains (generally about 90 to 100%) positive; (+), many strains (generally about 75 to 90%) positive; V, strain-to-strain variation (generally about 25 to 75% positive); (—), many strains negative (generally about 10 to 25% positive); —, most strains negative (generally about 0 to 10% positive); ND, no data.

Other Genera That Have Been Included in The Family Vibrionaceae

The four genera *Vibrio*, *Photobacterium*, *Aeromonas*, and *Plesiomonas* are the well-established genera of Vibrionaceae; however, a number of other genera have been classified in the family by various authors. Two of the proposed genera (*Enhydrobacter* and *Halomonas*) contain organisms that are very different phenotypically from the four well-established genera. Inclusion of these organisms would require a drastic change in the definition of the family. Several of the genera (*Beneckea*, *Listonella*, and *Oceanomonas*) were proposed to subdivide the genus *Vibrio*. In addition, there are a number of genera, species, and unnamed organisms in the older literature that probably belong in the family, perhaps in one of the currently accepted genera or species. All of the genera are discussed alphabetically below.

The Genus *Allomonas*

Kalina et al. (1984) isolated 24 strains of an oxidase-positive fermentative organism that had some properties of *Aeromonas* and some of *Vibrio*. The strains came from feces of healthy humans (12 strains), river water (6), and sewage (6). Kalina et al. (1984) did a numerical taxonomic analysis and defined them as “group II.” By DNA-DNA hybridization, the strains were not closely related to *Aeromonas hydrophila*, *Plesiomonas shigelloides*, *V. cholerae*, or eight other species in the family Vibrionaceae. Based on these data, they proposed a new genus *Allomonas* in the family Vibrionaceae with a single species, *A. enterica*. However, they also mentioned that this new organism was similar in many ways to a new species in the genus *Vibrio*, *V. fluvialis*. They did not study *V. fluvialis* because

strains were not available at the time their study was done. The name *Allomonas* appeared in the literature for a brief time, but strains of *A. enterica* were later found to be identical to *V. fluvialis* by DNA hybridization and phenotypic analysis (Subcommittee, 1986). Thus, *V. fluvialis* is a senior synonym of *A. enterica*, and the latter name has not been used in the literature. Today, the genus *Allomonas* could be proposed again in an attempt to subdivide the genus *Vibrio*.

The Genus *Beneckea*

The genus *Beneckea* was proposed as a new genus in the seventh edition of *Bergey's Manual of Determinative Bacteriology* (Campbell, 1957). It was originally classified in the Family Chromobacteriaceae (Table 2) (Breed et al., 1957). *Beneckea* included six species: *B. labra* (the type species) *B. ureasophora*, *B. chitinovora*, *B. hyperoptica*, *B. indolthetica* and *B. lipophaga*. It was defined to be a genus of rod-shaped bacteria that were Gram-negative, had peritrichous flagella, fermented carbohydrates, and digested chitin. The strains were from sea water, marine mud, brackish water, and soil. However, the genus name *Beneckea* was used very rarely until the 1970s.

Baumann et al. (1971) studied a large group of vibrios isolated in the Pacific Ocean near the Hawaiian Islands. They defined four new species of “marine vibrios” and classified them all in the genus *Beneckea*—*Beneckea campbellii*, *B. neptuna*, *B. nereida* and *B. pelagia*. They also expanded the definition of *Beneckea* to include *Vibrio alginolyticus* (*Beneckea alginolytica*) and *V. parahaemolyticus* (*Beneckea parahaemolytica*). Over the next few years, other species of *Beneckea* were described, and from 1971 until the mid-1980s the name *Beneckea* frequently appeared in the literature, often used as a synonym for “marine *Vibrio* species.” However, as additional species of *Beneckea* were described or

characterized in more detail, the genus became almost as heterogeneous as the genus *Vibrio* had been, so reference is not an exact match. Baumann et al. (1980) proposed that the genus *Beneckea* be abolished and that all the *Beneckea* species be classified in the genus *Vibrio*. The name *Beneckea* still occasionally appears in the literature, but most authors have accepted the proposal of Baumann et al. (1980b) and classify all the “marine vibrios” in the genus *Vibrio*.

The Genus *Enhydrobacter*

The genus *Enhydrobacter* was included in the family Vibrionaceae by Staley et al. (1987) and contains a single species, *E. aerosaccus*. This organism is quite different from all other species in the family because it contains intracellular gas vacuoles (Fig. 4).

Van Ert and Staley (1971) isolated gas-vacuolated organisms from the oxygen-depleted thermocline of Wintergreen Lake, a eutrophic lake near Kalamazoo, Michigan. Water from the lake was enriched in a dilute peptone solution and then plated on media with low concentrations of organic carbon. After the plates had been incubated for a month, a colony was picked because it had a morphology typical of bacteria that form gas vacuoles. Their description of the organism included the following properties: small Gram-negative rod; nonmotile, no flagella;

intracellular gas vacuoles produced under certain conditions (Fig. 4); GC content of DNA of 66.3 mol%; poor or no growth on most rich laboratory media (generation time of 25 in a medium containing 0.1% glucose, 0.1% vitamin-free casamino acids, vitamins, and other ingredients), no sugar fermentation when done with enteric fermentation bases, weak acid production from fructose and xylose in the “OF fermentation base” of Hugh-Leifson; no growth in most media used to identify isolates in clinical microbiology laboratories; biotin and folic acid required for growth; oxidase positive; catalase positive; 21 of 42 carbon sources utilized when tested in a medium low in organic matter; indole negative; nitrate reduced only as far as nitrite; growth in both the presence and absence of oxygen (roll tube technique); growth at 25–41°C but not at 7 or 43°C; gas vacuoles produced during most growth conditions but produced better in liquid media under reduced oxygen tension. Van Ert and Staley (1971) thought that the genus *Achromobacter* was most appropriate for this unusual organism. However they later studied it by DNA-DNA hybridization (Staley et al., 1987) and found that it was 0–1% related to several species of Enterobacteriaceae, *Vibrio*, and to *Plesiomonas shigelloides*; 9% related to *Vibrio cuneatus* (a nonfermentative organism that is no longer classified in *Vibrio*); but the highest relatedness was to *Aeromonas*. It was 11–13% related to *Aeromonas hydrophila* and 14–22% related to three other *Aeromonas* species. Relatedness to other organisms was not studied. A single strain was used to define a new genus, *Enhydrobacter*, with a new species *E. aerosaccus*, which was classified in the family Vibrionaceae (Staley et al., 1987). The type strain was designated as ATCC 27094.

No DNA-RNA hybridization or RNA sequence work has been done on *E. aerosaccus*, so its relationship to other organisms in the family Enterobacteriaceae and Vibrionaceae is uncertain. Further studies are needed to better define its closest relatives. Phenotypically, it is quite different from all the species currently included in the family Vibrionaceae.

Our laboratory examined the type strain of *E. aerosaccus* and found that it grew lightly on supplemented tryptone glucose extract (TGE) agar (van Ert and Staley, 1971), but did not grow in any of the test media used for the routine identification of Enterobacteriaceae and *Aeromonas*. It did not grow on sheep blood agar at 36°C. Phenotypically, this organism would be a strange member of the family.

The Genus *Halomonas*

Vreeland et al. (1980) isolated nine strains of an unusual bacterium from solar condensers at the

Fig. 4. Cell morphology of *E. aerosaccus* showing gas vacuoles. (A) Appearance under phase microscopy; the refractile (white) regions are the gas vacuoles. The cells were grown on Hugh-Leifson medium. (B) Same as A, except the cells were grown in tryptone-glucose extract broth plus 0.1% yeast extract. The cells are longer. (C) Electron micrograph of cells grown in low-carbon media. (All redrawn from Figures 1, 2, and 3 of van Ert and Staley, 1971.)

Antilles International Salt Company facility on Bonaire, Neatherlands Antilles (Vreeland et al., 1980). They did a number of phenotypic tests and compared their strains to other salt-requiring bacteria. Based on differences among their strains and other halophilic bacteria, they proposed a new genus, *Halomonas* (Vreeland et al., 1980). *Halomonas* had a single species, *Halomonas elongata*, and was classified in the family Vibrionaceae. The original description of *Halomonas* indicated that it fermented rather than oxidized sugars and other carbohydrates. However, it was later found that *Halomonas* is a nonfermenter rather than a fermenter (Subcommittee, 1986). Vreeland (1984) subsequently removed *Halomonas* from the family Vibrionaceae and classified it with the Gram-negative aerobic rods and cocci as a genus of uncertain affiliation (not belonging to a specified family) (see The Family Halomonadaceae in this Volume).

The Genera *Listonella* and *Shewanella*

MacDonnell and Colwell (1985) studied the structure of 5S rRNA of many species of Vibrionaceae and other organisms and used cluster analysis to group species with similar rRNA sequences. Their data indicated that some of the species were more closely related to each other than to other organisms. Based on this criterion alone, they established two new genera in the family—*Listonella* and *Shewanella*. The proposal of *Listonella* was an attempt to subdivide the genus *Vibrio*, and the proposal of *Shewanella* was an attempt to reclassify *Pseudomonas putrefaciens* and group it with other organisms.

THE GENUS LISTONELLA *Listonella* was established around its type species *Listonella anguillarum* (*Vibrio anguillarum*), and included *L. damsela* (*V. damsela*) and *L. pelagia* (*V. pelagius*). It was defined almost entirely on the basis of rRNA structure and included only the following definition: “curved rods, Gram negative, motile by monotrichous or peritrichous flagella. Chemoorganotrophic, oxidase positive, associated with marine environments. Generally pathogenic for fish or eels. Do not grow at 40°C. Require NaCl for growth. GC mol% 43–46.” Interestingly, *Listonella* did not include *V. ordalii* which is highly related to *V. anguillarum* by DNA hybridization (see The Genera *Vibrio* and *Photobacterium* in this Volume) and is the only close relative based on this technique.

THE GENUS SHEWANELLA For many years it was known that *Pseudomonas putrefaciens* is a Gram-negative nonfermentative bacterium that can easily be isolated from the marine environment. This

organism has been classified in both *Pseudomonas* and *Alteromonas*. The proposal of reference is not an exact match MacDonnell and Colwell. (1985) classified this organism in the new genus *Shewanella*. *Shewanella* was established around its type species *Shewanella putrefaciens* (*Pseudomonas putrefaciens* = *Alteromonas putrefaciens*), and included *Shewanella hanedai* (*Alteromonas hanedai*) and a new species *Shewanella benthica*, which was also described in this paper (MacDonnell and Colwell 1985). The definition of *Shewanella* was also based almost entirely on rRNA structure, and included only the description “straight or curved rods, Gram negative, non-pigmented, motile by polar flagella. Chemoorganotrophic, oxidase positive, generally associated with aquatic or marine habitats. GC mol% 44–47.” The inclusion of *Shewanella* in the family Vibrionaceae would drastically alter the definition of the family to include nonfermentative species. Traditionally, the family has included only fermentative species.

The Genus *Lucibacterium*

Lucibacterium was proposed by Hendrie et al. (1970) and was included as “Genus V” of the family Vibrionaceae in the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Buchanan and Gibbons, 1974). *Lucibacterium* contained a single species, *Lucibacterium harveyi* (*Vibrio harveyi*), and can be considered an attempt to subdivide the bioluminescent vibrios. *Lucibacterium* was used occasionally in the literature, but rarely in the last few years.

The Genus *Oceanomonas*

Oceanomonas was proposed by Miyamoto et al. (1961) and classified as a new genus in the family Vibrionaceae. The type species for *Oceanomonas* was designated as *O. enteritis* (= *Vibrio parahaemolyticus*) and it also included *Oceanomonas alginolytica* (*Vibrio alginolyticus*). The main purpose of this proposal was to separate the halophilic species of *Vibrio* from *V. cholerae*, the nonhalophilic type species for the genus. The proposal of a separate genus for these two species had considerable merit because they are closely related to each other and distantly related to *V. cholerae* (see The Genera *Vibrio* and *Photobacterium* in this Volume). The grouping of these two related species into a separate genus would be the first logical step in splitting the genus *Vibrio* into phylogenetic units. However, the name *Oceanomonas* no longer has standing in nomenclature and has rarely been used in the literature.

Bacteria that Digest Agar and Alginic Acid

In much of the older literature, bacteria that digest agar or alginic acid received special atten-

tion, and genera were set up to include all strains that digested one of these polysaccharides. The seventh edition of *Bergey's Manual of Determinative Bacteriology* (see Table 2) recognized the genera *Agarbacterium*, *Alginobacter*, and *Alginomonas*. Strains representing these genera are not readily available today, but many of them are probably species of Vibrionaceae and some are undoubtedly "marine vibrios." The genera were very poorly defined, and one key property was the type of flagellation, either polar or peritrichous. Some genera even contained both fermentative and nonfermentative species.

THE GENUS ALGINOBACTER The genus *Alginobacter* was proposed by Thjtta and Kss (1945) and the genus name first appeared in the seventh edition of *Bergey's Manual of Determinative Bacteriology* and was classified in the family Enterobacteriaceae. The type species was *Alginobacter acidofaciens* which was the only species listed. The description included: short rods that are motile by peritrichous flagella; acid and gas produced from glucose and alginic acid; variable fermentation of other carbohydrates; citrate and alginate used as sole sources of carbon; indole negative; acetylmethyl carbinol produced (weakly); nitrate reduced to nitrite; and growth at 4, 30, 37, and 45°C.

All five strains of *A. acidofaciens* were isolated from soil. It is difficult to determine the positions of *Alginobacter* today but it appears to belong in the family Enterobacteriaceae (if the strains were oxidase negative). It is not possible to rule out the possibility that *Alginobacter acidofaciens* was a marine vibrio, since alginic acid is usually found in the marine environment.

THE GENUS ALGINOMONAS *Alginomonas* was proposed by Thjtta and Kss, (1945) and this genus was listed in the seventh edition of *Bergey's Manual* (see Table 2). The type species was *Alginomonas nonfermentans* and four other species were included—*A. terrestrealginica*, *A. alginovora*, *A. fucicola*, and *A. alginica*. The species of *Alginomonas* were described as being "fluorescent, Gram negative, coccoid rods with one to four polar flagella, not utilizing carbohydrates, and found on algae and in sea water and soil." The nonfermentative nature of *Alginomonas* would exclude it from the family Vibrionaceae; however, the name *Alginomonas alginica* was also used for an organism that ferments carbohydrates.

THE GENUS ALGINOVIBRIO The genus *Alginovibrio* was proposed by Thjtta and Kss (1945) for a group of alginic acid-digesting, vibrio-like bacteria isolated from sea water. No species were named, although four were

described. Formal nomenclatural proposals were made by Meland (1963), who designated *Alginovibrio aquatilis* as the type species of the genus, and named two other species, *A. norvegicus* and *A. immotus*. The species of *Alginovibrio* all were fermenters and vibrio-like, so would probably be members of Vibrionaceae. The name *Alginovibrio* has rarely been used.

THE GENUS Agarbacterium The genus *Agarbacterium* was proposed by Angst (1929) and it was included in the seventh edition of *Bergey's Manual of Determinative Bacteriology*. Carbohydrates were said to be "feebly attacked, if at all, some species producing acid but no gas," so it is unclear whether strains of *Agarbacterium* were fermenters or non-fermenters. However, most strains that digest complex carbohydrates are fermenters. Other properties included: short to medium-sized rods, motile by peritrichous flagella or non-motile, pigments may be produced, and alginates may be digested. The type species was designated as *Agarbacterium aurantiacum* (Angst, 1929).

Habitats

Species of the family Vibrionaceae occupy many different ecological niches (Baumann and Baumann, 1981; Campbell, 1957; Sakazaki and Balows, 1981; Simidu and Tsukamoto, 1985). They cause disease of humans and animals and also occur in the environment. Many factors probably govern their distribution, but four of the most important are: the particular animal or plant hosts, temperature, salinity, and depth below the surface for the species that are found in the ocean (Simidu and Tsukamoto, 1985). A few species are clearly host-adapted. *Vibrio cholerae* serogroup O1 is usually limited to humans where it causes cholera. *Aeromonas salmonicida* is adapted to salmonid fish where it causes illness and death. *Photobacterium leiognathi* is usually isolated from fish in shallow tropical water, but *P. phosphoreum* is usually found in the luminous organs of fish that live at depths of 200–1,200 (Hastings and Nealson, 1981). Until recently, strains of *P. angustum* had been isolated only from water samples taken off the coast of Hawaii. More details about the habitats of various species are given in the following two chapters.

Isolation

Many of the species of Vibrionaceae are easy to isolate because they grow well on the ordinary peptone-type media used in general and clinical microbiology (Baumann and Baumann, 1981). Table 5 lists some of the general and selective

Table 5. The usefulness of common media for the isolation of the four genera of the Vibrionaceae.^a

Medium	Usefulness for: ^b

^aSee The Genera *Vibrio* and *Photobacterium* and The Genera *Aeromonas* and *Plesiomonas* in this Volume for more details.

^bThe symbols “+” to “++++” and “—” indicate the general usefulness of the medium and apply to most species in the genus; however, some species and strains may be exceptional and may differ on a particular medium. For example, most strains of *Vibrio cholerae* do not grow well on TCBS agar (see The Genera *Vibrio* and *Photobacterium* and The Genera *Aeromonas* and *Plesiomonas* in this Volume). A blank space indicates that data are not available or are contradictory.

^cMost of the media formulated for *Vibrio* isolation were specifically designed to isolate *V. cholerae*.

media, which are discussed in more detail in The Genera *Vibrio* and *Photobacterium* and The Genera *Aeromonas* and *Plesiomonas* in this Volume. Most strains have been isolated from human or animal clinical specimens, fresh water, or salt water close to the shore. Collecting water samples can be done with a number of commercial sampling devices, or simply with a sterile container tied to a string.

Samples are collected and then plated (in the field or in the laboratory) onto solid media and/or placed in liquid enrichments. The incubation temperature and NaCl content of the medium are two important variables to consider in isolation. A few species are clearly psychrophilic and do not even grow at 25°C. Other species grow well at 25°C but not at 35–37°C, the temperature commonly used in clinical laboratories. Most species of Vibrionaceae grow in commercial peptone media that contain 0.5 to 0.85% NaCl in their formulas, but a few require a higher concentration for growth.

Identification

The first and most important step in identification is to determine that a clinical or environ-

mental isolate is probably a member of the family Vibrionaceae. Tables 3 and 4 list some of the properties that are suggestive. The next step is usually to identify the isolate to the species level by a variety of phenotypic tests that are described in The Genera *Vibrio* and *Photobacterium* and The Genera *Aeromonas* and *Plesiomonas* in this Volume.

Human Clinical Isolates

About half the species of Vibrionaceae occur in human clinical specimens, and their identification is not difficult. Strains of Vibrionaceae are rare, however, compared to Enterobacteriaceae, so laboratory personnel may not be as familiar with them. Commercial identification systems have not been as successful in identifying Vibrionaceae as they have been with Enterobacteriaceae (Farmer et al., 1985). However, many manufacturers have now obtained strains of Vibrionaceae and improved the accuracy of their product. Identification of Vibrionaceae with these commercial kits will likely continue to improve with time. *Vibrio cholerae* O1, *V. cholerae* non-O1, *V. parahaemolyticus*, *V. alginolyticus* and the *Aeromonas hydrophila* group are the most common clinical isolates. Identification of

these species is not difficult, regardless of the method used.

Environmental Isolates

Identification of environmental isolates can be much more difficult because this group has not been studied as well as the clinical group. Identification of *Aeromonas* and *Plesiomonas* strains is not difficult, and can be done with the same media and methods used for clinical isolates. Identification of *Vibrio* and *Photobacterium* isolates is more difficult and requires special media and methods because of their special temperature and ionic requirements.

Computer Identification

Because many of the species of Vibrionaceae are similar in their phenotypic properties, several computer programs have been developed in our laboratory for the routine identification of *Aeromonas*, *Plesiomonas*, *Vibrio*, and *Photobacterium* isolates. The programs are based on mathematical analysis of the results of 45 to 50 simple biochemical tests. The test media are inoculated and read at one and two days (and up to seven days if desired). Each test is coded as "+" or "-" for the computer, which then compares the profile of the unknown strain with all the organisms in the data base. The approach is based on the normalized likelihood calculation described by LaPage (1974). Two different programs are used: The first, named "George," is used for all the species of Enterobacteriaceae and for the species of Vibrionaceae that grow well at 35–37°C in media with no added salt (0.5–1.0% NaCl). A second program, named "Neptune," was designed specifically to identify the halophilic species of *Vibrio* and *Photobacterium*. The biochemical tests used in this program have marine cations added to give a higher content of Na⁺, K⁺, and Mg⁺⁺, and all incubations are done at 25°C since many of these species do not grow well at 35–37°C. Originally these computer programs were written in FORTRAN computer language and run on a mainframe computer. However, because many potential users did not have access to a mainframe computer, the programs were rewritten in BASIC computer language for microcomputers that are IBM compatible and have the DOS operating system. Interested persons should write to J. J. Farmer to obtain further information for obtaining these. We find that both programs are extremely useful for comparing a clinical or environmental isolate with a large data base of species, biogroups, and individual strains.

Details on the characteristics of the various genera of the Vibrionaceae are given in Chapters 157 and 158.

The Genera *Vibrio* and *Photobacterium*

J. J. FARMER III AND F. W. HICKMAN-BRENNER

Introduction

Both *Vibrio* and *Photobacterium* are old genera that were described in the 1800s. The genus name *Vibrio* was coined by Pacini in 1854 during his studies on cholera, and it is one of the oldest names for a bacterial genus. Pacini also named the cholera bacillus, which eventually became *V. cholerae*, the type species for the genus *Vibrio*. Much of the history and literature on *Vibrio* came from medical microbiology and concerned cholera and other similar vibrios that early bacteriologists had difficulty in differentiating from the true cholera bacillus. In contrast, the genus name *Photobacterium* was coined by Beijerinck (188a) who was interested in environmental microbiology. Most of the literature on *Photobacterium* and on the marine species of *Vibrio* has come from environmental microbiologists, particularly those studying bacteria found in the sea. Unfortunately, there has been a poor interchange of ideas, information, and bacterial cultures between these two disciplines, which has led to considerable confusion in the literature. The methods for isolation and identification used by the two groups of workers are quite different and add further confusion. Several of the *Vibrio* species are very important in human or animal disease, and many of the species of *Vibrio* and *Photobacterium* are widely distributed in the environment. Many papers review various aspects of the two genera including: animal diseases (Anderson and Conroy, 1970; Baross et al., 1978; Sinderman, 1970); basic biology (Baumann and Baumann, 1977); enzyme structure and function (Bang et al., 1978b; Baumann and Baumann, 1973, 1978; Crawford, 1975; Gee et al., 1975); cellular structure or composition (Eberhard and Rouser, 1971); ecology and distribution (Golten and Scheffers, 1975; Harrell et al., 1976); human infections (Blake et al., 1979; Ryan, 1976; Wachsmuth et al., 1980; World Health Organization Scientific Working Group, 1980); physiology and metabolism (Doudoroff, 1942b; Eagon and Wang, 1962; Gauthier, 1976; Humm, 1946; Ingra-

ham, 1962; Payne et al., 1961; Richter, 1928; Stanier, 1941); nucleic acid structure, function, or relatedness (Baumann and Baumann, 1976; Schiewe et al., 1977); nutrition (Doudoroff, 1942a); symbiotic relationships (Reichelt et al., 1977; Ruby and Morin, 1978); and taxonomy (Baumann et al., 1971a; Baumann et al., 1984; Fitzgerald, 1977; Hendrie et al., 1970; Reichelt and Baumann, 1975; Shewan and Véron, 1974; Singleton and Skerman, 1973).

History

The Concept of “Marine Vibrios”;
Requirement for Na⁺ and Other Ions
(Baumann and Baumann, 1981)

The first comprehensive study of bacteria indigenous to the oceans was done by Bernhard Fischer (1894) of the University of Kiel. His major conclusions have been confirmed and extended by numerous investigators who have shown that the majority of the heterotrophic bacteria in the open oceans are Gram-negative, straight or curved rods or spirals that are usually motile by means of flagella (Baumann et al., 1971a, 1972; MacLeod, 1965, 1968; Pfister and Burkholder, 1965; Sieburth, 1979). Most of these organisms are eubacteria and have rigid cell walls. Fischer (1894) made the important observation that the highest viable counts (plate counting method) were obtained when seawater or 3% NaCl was included in the nutrient medium. This finding was subsequently interpreted to be primarily an osmotic phenomenon, since many marine bacteria were found to lyse in dilute media (Harvey, 1915; Pratt, 1974). However, Richter (1928) clearly demonstrated a specific Na⁺ requirement for the growth of a marine luminous strain and, in addition, showed that complex media were not suitable for establishing this requirement since they contain substantial levels of inorganic ions (for reviews dealing with the early literature, see Larsen, 1962; MacLeod, 1965, 1968). Since these results were overlooked, and complex media continued to be used, considerable controversy persisted concerning the presence and stability

of this character. MacLeod independently reestablished the early findings of Richter and developed synthetic media for testing the presence of a Na^+ requirement (MacLeod, 1968). The extensive application of these methods has since established that all or most Gram-negative marine bacteria have a specific requirement for Na^+ (Baumann et al., 1971a, 1971b, 1972, 1973; Hidaka and Sakai, 1968; MacLeod, 1965, 1968). Furthermore, the work of MacLeod (1968) and others (reviewed by Pratt, 1974) has indicated the genetic stability of this requirement. Using 31 different marine isolates, including seven species of facultative anaerobes (with GC contents of 39–48 mol%), 12 species of nonfermentative marine organisms (with GC contents in their DNAs of 30–68 mol%), and one strain of a marine host-independent *bellovibrio*, Reichelt and Baumann (1974) studied the effect of NaCl concentration on growth rate and cell yield in media containing 50 mM Mg^{++} and 10 mM Ca^{++} (marine medium) and 2 mM Mg^{++} and 0.55 mM Ca^{++} (terrestrial medium). The optimum growth rates and cell yields in the marine medium ranged from 70 to 300 mM NaCl, while the optima in the terrestrial medium ranged from 100 to 460 mM. In many strains, the higher concentrations of Mg^{++} and Ca^{++} present in the marine medium reduced the amount of NaCl required for optimal growth rate and yield and decreased the generation time. Some strains did not grow unless the medium contained the higher Mg^{++} and Ca^{++} concentrations, indicating that the addition of 3% NaCl to a terrestrial medium will not make it suitable for the cultivation of many common marine bacteria. The extent to which the Na^+ requirement may be partially reduced by other ions differs considerably among marine isolates (MacLeod, 1965, 1968; Pratt, 1974). In the case of *Alteromonas haloplanktis* (the organism used in the extensive studies of MacLeod and his collaborators), Li^+ has little or no sparing effect, while in the case of *Vibrio parahaemolyticus*, this ion is able to considerably reduce the concentration of Na^+ required (Morishita and Takada, 1976).

Detailed studies of the physiological basis of the Na^+ requirement have so far been restricted to a strain of the species *Alteromonas haloplanktis*. In this organism Na^+ is essential for: 1) the function of all the examined permease systems which include those involved in the uptake of amino acids, tricarboxylic acid cycle intermediates, galactose, orthophosphate, and K^+ (Thompson and MacLeod, 1973); and 2) maintenance of the integrity of the cell wall (Forsberg et al., 1970). Conclusion (1) has been extended to the marine species *Vibrio fischeri* (Drapeau et al., 1966) and to *Pseudomonas doudoroffii* which requires 75mM Na^+ for the optimal rate of

uptake of D-fructose (Baumann and Baumann, 1981). Conclusion (2) has also been extended to an *Alteromonas espejiana* strain, the host of the lipid-containing, marine bacteriophage PM-2 (Baumann and Baumann, 1981). In a recent survey of the effect of Na^+ on the integrity of the cell wall, it was found that in the absence of this ion a weakening of the outer membrane occurred in 14 of 20 marine strains examined. These observations suggest that the requirement for Na^+ by marine bacteria is a complex, multigenic trait which would not be readily lost by mutation. In contrast to the marine bacteria and the extreme halophiles which require over 3 M Na^+ (Larsen, 1962), the growth of most Gram-negative terrestrial organisms does not appear to be Na^+ dependent. Where a requirement has been demonstrated it has generally been found to be considerably lower than that observed in marine bacteria and may only be present under certain conditions of cultivation (Kodama and Tanaguchi, 1976; Reichelt and Baumann, 1974). An interesting exception are the rumen bacteria, which live in an environment having a relatively high concentration of this ion (Caldwell and Hudson, 1974; Reichelt and Baumann, 1974). The level of the Na^+ requirement and its stability imply that marine bacteria would not be able to colonize most terrestrial habitats. Conversely, there is considerable evidence that Gram-negative terrestrial bacteria do not survive in the marine environment (Jannasch, 1968; Moebus, 1972). These observations suggest an ecological separation of Gram-negative marine and terrestrial organisms as a consequence of specific adaptations to their respective habitats. In the case of marine bacteria, this attribute was probably acquired as a result of physiological adaptations to life in an environment having a relatively constant ionic composition. In this context, it is curious that many marine bacteria appear to grow better at 50–75% seawater than at 100% concentration (Gundersen, 1976) and that the optimal concentration of Na^+ (70–300 mM) for the growth of a number of marine isolates is considerably lower than the Na^+ concentration in seawater (450–480 mM) (Reichelt and Baumann, 1974). No obvious correlation has been observed between the source of isolation of the strains and the amount of Na^+ necessary for optimal growth.

Another fundamental question is whether there are bacterial species unique to the marine environment. Stanier (1941) succinctly formulated this problem and proposed an experimental solution, the essence of which was a comparison of the bacterial flora with similar biological functions (e.g., mineralization of simple organic compounds) in both marine and terrestrial habitats. The application of this approach has been facilitated by the existence of relatively

specific enrichment methods for the isolation of terrestrial pseudomonads as well as by the extensive phenotypic characterization of these organisms, which allows the ready identification of species (Stanier et al., 1966). In utilizing enrichment methods for the isolation of marine bacteria, it is essential to use seawater samples obtained aseptically at locations where contamination by terrestrial organisms is minimal or absent. Using these precautions, it could readily be demonstrated that when a marine inoculum was used in enrichment cultures selective for certain species of terrestrial pseudomonads, the resulting flora consisted of facultative anaerobes and nonfermentative organisms which were different from terrestrial species (Baumann et al., 1971a, 1971b, 1972, 1973; Reichelt and Baumann, 1973). These results established that the mineralization of simple organic compounds in the ocean is done by a bacterial flora that is different from those with this role in terrestrial habitats. This may not apply to estuarine habitats, since these environments are complex with respect to the diversity of habitats, salinity, availability of nutrients, and contamination by terrestrial organisms. The designation of a species as "estuarine" has no real conceptual meaning since it is not yet known whether there are any species indigenous to estuaries or other coastal habitats. Since the open oceans contain relatively low concentrations of bacteria relative to those found directly off shore, the inability to detect a particular species in the open ocean may simply be due to the limitation of sample size.

About 50% of the oceans (by area) reach depths where the pressures range from 380 to 1,100 atmospheres (ZoBell, 1963). Consequently, an important question has been the possible existence of bacteria which are specifically adapted to life at high hydrostatic pressures and which would be inhibited or killed by exposure to one atmosphere. The resolution of this problem has been undertaken by H. Jannasch and his collaborators who have constructed special samplers which allow the cultivation of marine microorganisms at the hydrostatic pressures at which they were sampled without introducing any decompression steps (Jannasch and Wirsén, 1977; Jannasch et al., 1976). Although detailed investigations of this problem are few, the initial results strongly suggest that if microorganisms specifically adapted to high pressures do exist, their numbers constitute a relatively small proportion of the total metabolically active, heterotrophic, bacterial flora of the deep oceans.

Over 90% of the marine environment (by volume) has a temperature below 5°C (ZoBell, 1963). Consequently, it is also of considerable interest to know whether the psychrophilic isolates from the ocean differ from previously char-

acterized mesophiles only in their relation to temperature or whether they actually constitute different species. An answer to this question should be readily obtained by application of the various methods used for the characterization of marine bacteria.

One practical consequence of the marine nature of most of the species of *Vibrio* and *Photobacterium* is shown in Table 1, which indicates that biochemical test results used for routine identification vary depending on the Na⁺ content of the media. The addition of NaCl usually results in an increase in the number of positive reactions and in the rapidity of the positive results.

History—Medical Aspects

The cholera bacillus, *Vibrio cholerae*, was first cultured by Koch in 1882 during an epidemic of cholera in India and Egypt. This led to an intensive study of the vibrios by many workers with the main goal of differentiating the "nonpathogenic" environmental and marine vibrios from the true cholera bacillus. No other pathogenic species of *Vibrio* were documented until 1950, when Fujino isolated *V. parahaemolyticus* from an outbreak of severe food poisoning in Osaka, Japan (see Fujino et al., 1974). Recently, a number of other species have been described and their role in causing human disease has been postulated or shown.

Nomenclature and Classification

In the last two decades the vibrios and photobacteria have changed from a poorly characterized heterogeneous group of organisms to several well-understood natural groups. This has been due to the transfer of "nonfermentative vibrios," "aerobic vibrios," and "microaerophilic vibrios" to other genera such as *Campylobacter* (*Vibrio fetus*), *Wolinella* (*Vibrio succinogenes*), *Pseudomonas*, and *Alteromonas* (Baumann and Baumann, 1981). The species currently recognized in *Vibrio* and *Photobacterium* are listed in Table 2. The genera *Vibrio* and *Photobacterium* are classified in the family Vibrionaceae along with two other genera, *Aeromonas* and *Plesiomonas*. Fig. 1 in Chapter 156 gives the gc content of the genera of vibrionaceae. It can be used as a first step in determining the relatedness of genera. *Vibrio* is closely related to *Photobacterium*, which is expected because of their phenotypic similarities, but these genera are more distantly related to *Aeromonas* and to the family enterobacteriaceae (Fox et al., 1980). These relationships were shown by nucleic acid hybridization experiments that are summarized in Fig. 1

^bTheoretically any of these species could be found in feces after the ingestion of seafood or water that contains them. Based on published data, this must be a rare event.

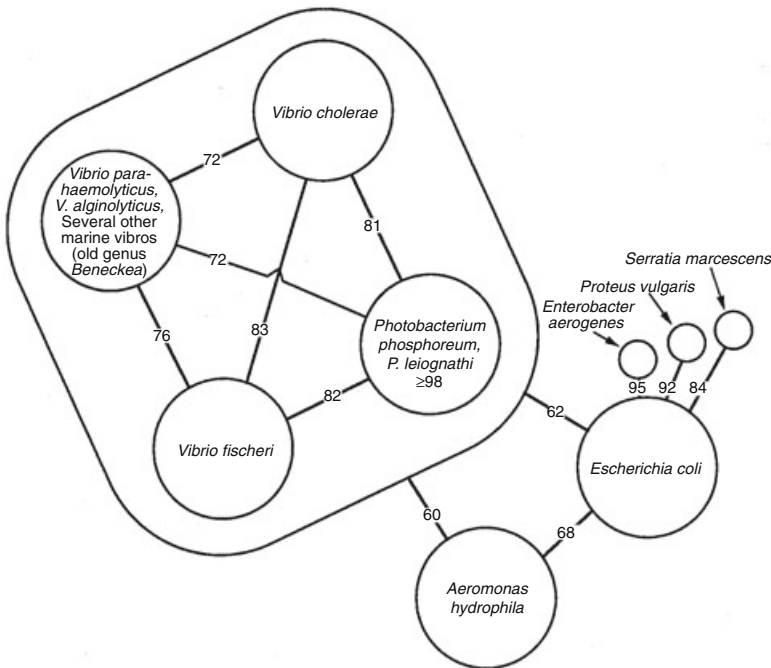

Fig. 1. Relatedness of the species of *Vibrio* and *Photobacterium* to each other and to other organisms in the families Enterobacteriaceae and Vibrionaceae based on the DNA-RNA hybridization studies of Baumann and Baumann and their coworkers. Numerical values represent average percent homologies. (Redrawn from Baumann and Baumann, 1981.)

Fig. 2. Related species in the genus *Vibrio* based on DNA-DNA hybridization. (Redrawn from our own data that was summarized by reference is not an exact match Brenner et al., 1983.)

(Baumann and Baumann, 1981). More distant relatives include the purple photosynthetic bacterium *Chromatium* and the nonfermentative genera *Pseudomonas* and *Acinetobacter* (see Fig. 3 in The Family Vibrionaceae in this Volume). Also Table 4 in The Family Vibrionaceae in this Volume lists some properties that differentiate the four genera in the family Vibrionaceae. Most of the *Vibrio* species are not closely related to each other in a phylogenetic sense (Baumann and Baumann, 1981; Baumann and Schubert, 1984; Brenner et al., 1983a). Thus, *Vibrio* is a heterogeneous genus, in a manner similar to the genus *Pseudomonas*. This is clear from DNA-DNA hybridization experiments that have been confirmed in several laboratories (Anderson and Ordal, 1975) and are shown in Figs. 2 and 3. Since *V. cholerae* is the type species for the genus, the genus definition must be built around it. *V. cholerae* is closely related to *V. mimicus*, but not closely related to the other vibrios (Fig. 2). However, another major evolutionary line includes several of the wellknown *Vibrio* species: *V. parahaemolyticus* is closely related to *V. alginolyticus* and greater than 30% related to several other species (Figs. 2 and 3). Most of the other species do not have close relatives, but there are a few exceptions: *V. fluvialis* with *V. furnissii*, *V. anguillarum* with *V. ordalii*, *V. splendidus* biogroup 1 with *V. splendidus* biogroup 2, *V. pelagius* biogroup 1 with *V. pelagius* biogroup 2, and *P. leiognathi* with *P. angustum* (Fig. 3). Even within a well-defined species there can be considerable divergence. For example, *V. gazogenes* contains three to four DNA hybridization groups (Fig. 4) (Farmer et al., 1988) that are almost identical in their phenotypic properties. Similar genetic com-

parisons based on a large number of strains have been done for only a few *Vibrio* species. The conclusions for relatedness in *Vibrio* based on nucleic acid hybridization generally agree with those based on protein structure (see Fig. 5.20 of Baumann et al., 1984). However, recent data based on RNA sequences have not been in agreement, and have led to some proposals that need to be confirmed in other laboratories and with different methods before they can be seriously considered.

Habitats

The species of *Vibrio* and *Photobacterium* are widely distributed in the marine environment, and a few species infect marine animals, particularly if they are stressed. In addition, 12 of the *Vibrio* species cause intestinal or extraintestinal human infections (Blake et al., 1979; Colwell, 1984) or have been isolated from human clinical specimens. *Photobacterium* species have been isolated from human clinical specimens.

Infections of the Intestinal Tract—Cholera and Other Diarrheas

Five of the *Vibrio* species appear to cause diarrhea in humans. *V. cholerae* is well known as the cause of cholera (Barua, 1970; Finkelstein, 1973; Politzer, 1959), which is a distinct clinical entity in its most severe form, but in its milder form may be hard to distinguish from other watery diarrheas. *V. parahaemolyticus* is a well-documented cause of acute gastroenteritis (Fujino et al., 1974; Miwatani and Takeda, 1976). More recently, *V.*

Numbers indicate the range of DNA homology values between different organisms. Circles that are not connected are related by 30% or less (circle size has no meaning). (Redrawn from Fig. 44 of Baumann and Baumann, 1981.)

Fig. 4. Subgroups in the species *Vibrio gazogenes* based on divergence values in DNA-DNA hybridization experiments (these values reflect unmatched DNA sequences).

fluvialis (Huq et al., 1980; Lee et al., 1981), *V. hollisae* (Hickman et al., 1982; Morris et al., 1982), and *V. mimicus* (Davis et al., 1981) have been implicated as causes of diarrhea. *V. furnissii* (Brenner et al., 1983b) has been isolated from a few individuals with diarrhea, but there is no evidence that it can actually cause diarrhea.

Extraintestinal Infections

Strains of *Vibrio* have been isolated frequently from certain extraintestinal infections but are rarely isolated from others. Table 3 summarizes the sources of cultures studied at the *Vibrio* Reference Laboratory, Centers for Disease Control (CDC) Atlanta, Georgia. *Vibrio* species are often isolated from blood, arm and leg wounds, infected eyes and ears, and from gallbladders removed at surgery. They are rarely reported from patients with meningitis or pneumonia or from infections of the reproductive organs or urinary tract (Tison and Kelly, 1984). Within the genus *Vibrio* there is a division among the species which cause intestinal infection and those

which cause extraintestinal infections (Table 2); however, this division is not absolute. The pandemic strain of *V. cholerae* (serogroup O1, cholera-toxin⁺) seems to be well-adapted to the human intestinal tract, and it is seldom found at other sites (Table 3). This is in contrast to other serotypes of this species *V. cholerae* non-O1) which occur at a variety of other sites. Similarly, *V. parahaemolyticus* also occurs mainly in gastroenteritis. Most of the reports of wound infections and septicemia due to this organism were really due to *V. vulnificus*, which had not been described at that time. *V. vulnificus* is an important cause of (often fatal) septicemia and wound infections (Blake et al., 1979, 1980b; Hollis et al., 1976). *V. damsela* (Love et al., 1981) also appears to cause human wound infections (Morris et al., 1982). *V. alginolyticus* (Blake et al., 1979) has been isolated from several types of soft tissue infections. *V. metschnikovii* is usually an environmental organism (Lee et al., 1978a), but has been isolated from a case of peritonitis in a patient with an inflamed gallbladder (Jean-Jacques et al., 1981), and from a few other specimens. Most of the infections caused by the marine species of *Vibrio* are associated with exposure to seawater.

THE MARINE ENVIRONMENT Since detailed taxonomic studies allowing precise identification of the species of *Vibrio* and *Photobacterium* isolated from this ecological niche are just beginning, generalizations concerning habitats and distribution of most species cannot be made. Baumann and Baumann (1981) (see Table 2 in their review) summarized the information available that appeared to be based on sound taxonomic criteria. They found that strains from

geographically diverse locations, which have been assigned to the same species on the basis of phenotypic similarities, were found to have in vitro DNA-DNA homologies greater than 80%. Most of the remaining species of marine enterobacteria and the nonfermentative marine eubacteria were isolated from the open ocean 10–35 miles off the coast of Oahu, Hawaii, at depths ranging from surface waters to 1,300 (Baumann and Baumann, 1981). Most of the sites had little or no obvious terrestrial contamination. Several of these *Vibrio* species have not been reported from other locations.

There are good data on the habitats of the bioluminescent bacteria, some of which are able to enter into symbiotic association with marine animals. A number of studies have appeared dealing with the ecology of luminous bacteria in seawater off the coast of San Diego, California (Ruby and Nealson, 1978), the Eastern Mediterranean, and the Gulf of Elat (Shilo and Yetinson, 1979; Yetinson and Shilo, 1979), as well as from two locations in the open ocean in the North Atlantic and over the Puerto Rico Trench (Ruby et al., 1980). The results of these studies show a species-specific pattern influenced by season, depth, geographical locale, and salinity. These investigations are important because they represent ecological studies in which marine bacteria could be identified to the species level. Shilo and Yetinson (1979) were able to observe a correlation between the ecology of the luminous organisms and their physiological attributes.

SIMPLE METHODS TO DETERMINE THE NaCl CONTENT OF ENVIRONMENTAL WATER Since many of the species of *Vibrio* and *Photobacterium* are

found in salt and estuary water, it is often desirable to quickly estimate salinity in order to decide where to sample, especially for inland waters. Two simple methods are given below that are particularly useful in the field. A quantitative method can be used when the specimen is returned to the laboratory.

Method 1—Silver Nitrate (AgNO_3) Method

This method takes advantage of the fact that NaCl is usually the main salt that contributes Na^+ in environmental water samples. Ag^+ reacts with Cl^- to form a dense white precipitate.

Dispense 1.0 ml of 1% silver nitrate solution (see below) into a disposable 13×100 mm test tube. Take a 0.1-ml sample of the liquid whose Na^+ content is desired and add it to the tube. A white precipitate will form almost immediately. The amount of precipitate will be proportional to the amount of NaCl present in the sample. An alternative method is to add a drop of the silver nitrate solution to the water and observe the intensity of the white precipitate formed.

This method actually measures the Cl^- content of the liquid, but for bacteriological media and water samples taken near the coast, this is close to the concentration of NaCl .

Silver nitrate solution,	1%
Silver nitrate (AgNO_3)	10 g
Water	1 liter

Dissolve the AgNO_3 in the water. Store in a brown bottle (or in a clear glass bottle that must be kept in the dark). In the presence of light, a brown-black precipitate will form. It is sometimes convenient to dispense 1-ml volumes into a rack of screw-cap tubes and store them in the dark until sampling is done.

Method 2—Dissolved Solids Meter

There are number of inexpensive pocket meters that measure conductivity or total dissolved solids and provide a convenient way to quickly determine the approximate Na^+ content of media and water samples.

Insert the pocket meter into the liquid sample and obtain a reading. Check this against a calibration curve based on different NaCl concentrations, and read the concentration of dissolved ions, which should approximate the concentration of NaCl .

Isolation

Much has been written about the isolation of both *Vibrio* and *Photobacterium* species. Two different sets of methods have been used, depending on whether the specimen (sample) was from a human clinical specimen or from the marine environment. Although species of *Vibrio* and *Photobacterium* will often grow on both kinds of media, the low Na^+ content (0.5 to 0.85%) of some media will prevent growth of some marine species. Only limited data exist on the growth of the species isolated from human diseases on many of the media traditionally used by marine microbiologists. In spite of these differences, several media are useful for all types of research with these genera.

Artificial Seawater Recipes

It is often desirable to have a medium with all of the inorganic constituents of seawater, but without organic compounds and toxic contaminants. Several artificial seawaters are useful for this purpose.

ARTIFICIAL SEAWATER #1—MACLEOD'S FORMULA

This artificial seawater is very easy to prepare. Its formula does not contain several of the ingredients found in other formulas for artificial seawater (some of these are trace metals that are probably present in the distilled water added). One advantage of this formula is that it does not form a precipitate when it is autoclaved. This medium should be satisfactory for most work with *Vibrio* and *Photobacterium*.

Artificial Seawater #1—MacLeod's Formula (CDC Medium 1425)

NaCl	23.38 g (0.4 Molar)
$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	24.65 g (0.1 Molar)
KCl	1.49 g (0.02 Molar)
$\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$	2.94 g (0.02 Molar)
Water	1 liter

Dissolve the ingredients in the water; a crystal-clear solution with a pH of about 6.6 will result. Dispense into screw-cap bottles or tubes. Autoclave at 121°C for 15 min. The final solution should be colorless and crystal clear. Store at room temperature.

ARTIFICIAL SEAWATER #2—"INSTANT OCEAN"

This is an artificial seawater that is prepared from a commercial packaged mix. It contains all of the ingredients found in seawater. Instant Ocean is available from Aquarium Systems, 33208 Lakeland Blvd., Eastlake, Ohio 44094, but it can also be found in many pet stores, particularly those that stock supplies for marine aquariums. It comes in several sizes, including a 1.6-lb package.

Artificial Seawater #2—Instant Ocean

Instant Ocean	40 g
Distilled water	1 liter
pH about 8.6.	

We find that this mix contains a variable amount of water that has been absorbed from the air. Forty grams of Instant Ocean per liter should give approximately normal oceanic salinity; more precise work may require a different amount that can be calculated based on "dry weight" or specific gravity.

Add the Instant Ocean to the water. Stir on a magnetic mixer for 15 to 20 min until all the salt dissolves. A colorless solution will result (sometimes with a slight amount of turbidity). If a sterile solution is needed, dispense and autoclave at 121°C for 15 minutes. Store at room temperature.

There are also several good general plating media for isolation of *Vibrio* and *Photobacterium*

(see below). Marine agar is a nonselective medium, and essentially all vibrios will grow on it. TCBS agar is a very selective medium, and many vibrios strains will grow on it. Most other bacteria are inhibited.

Marine Agar

Marine agar is a useful medium for the isolation and growth of organisms whose natural habitat is marine or other environments with a high content of Na^+ . It is particularly useful for the species of *Vibrio* and *Photobacterium* that require Na^+ in amounts higher than the usual content of bacteriological media, which is 0.5 to 1.0%.

Marine Agar

The formula used by Difco Laboratories (Catalog no. 0979) is given below; it is available as a dehydrated powder.

Peptone (Bacto)	5 g
Yeast extract	1 g
Ferric citrate	0.1 g
Sodium chloride	19.45 g
Magnesium chloride	8.8 g
Sodium sulfate	3.24 g
Calcium chloride	1.8 g
Potassium chloride	0.55 g
Sodium bicarbonate	0.16 g
Potassium bromide	80 mg
Strontium chloride	34 mg
Boric acid	22 mg
Sodium silicate	4 mg
Sodium fluoride	2.4 mg
Ammonium nitrate	1.6 mg
Disodium phosphate	8 mg
Water	1 liter
Agar	15 g

Add 55.1 g of Difco marine agar (or the recipe given above) to the distilled water and heat to boiling. pH 7.6 ± 0.2 at 25°C . Dispense into tubes or bottles and autoclave at 121°C for 15 minutes. A brown gelatinous precipitate is produced during autoclaving which settles to the bottom. Cool the flask to $45\text{--}50^\circ\text{C}$ and mix the flask contents to disperse the brown precipitate as much as possible. Pour into petri dishes and allow to harden and cool to room temperature. The bottom of the plates will contain some brown precipitate, which should not be confused with bacterial growth.

TCBS (Thiosulfate-Citrate-Bile Salts-Sucrose) Agar

This medium is extremely useful for isolating *Vibrio cholerae* and *V. parahaemolyticus* from diarrheal stool specimens. It is also used as a general isolation-plating medium for vibrios from clinical specimens and from the environment (Table 4, Fig. 5). Some *Vibrio* species do not grow or grow poorly on TCBS agar. Dehydrated TCBS medium is available from BBL, Eiken, Oxoid, and Gibco. These manufacturers may use different peptones (polypeptone by

Fig. 5. Growth of vibrios on TCBS agar; 0.01 ml of seawater collected about 10 m from shore was plated and incubated for 3 days at ambient temperature (about 25°C); note the different sizes, shapes, and colors of the colonies.

BBL, Proteose Peptone no. 3 by Difco, Eiken Peptone by Eiken, etc.), and the selectivity of the medium will vary from manufacturer to manufacturer and from lot to lot from the same manufacturer. Quality control should be done on each new lot number.

TCBS Agar

This is the recipe given by BBL for their TCBS agar.

Yeast extract	5 g
Pancreatic digest of casein	5 g
Pancreatic digest of animal tissue	5 g
Sodium citrate	10 g
Sodium thiosulfate	10 g
Oxgall, dehydrated	5 g
Sodium cholate	3 g
Sucrose	20 g
Sodium chloride	10 g
Ferric citrate	1 g
Thymol blue	40 mg
Brom thymol blue	40 mg
Agar	14 g
Water	1 liter

Suspend 88 grams of the dehydrated powder in 1 liter of cold water and heat gently with frequent agitation to boiling to dissolve the agar. pH 8.6 ± 0.2 . Do not overheat or autoclave. Cool to $45\text{--}50^\circ\text{C}$ and pour into petri dishes.

There are also several good liquid media for isolating or growing vibrios. One recipe is given below.

Alkaline Peptone Water (CDC Medium 1494)

This medium is used for enriching for *Vibrio cholerae* and other *Vibrio* species. Species of

Vibrio grow better than most other organisms at this high pH. They also tend to grow better than other organisms at the aerobic surface of the liquid. Enrichment in alkaline peptone water is usually followed by plating a loopful from the surface onto TCBS agar or onto similar plating medium selective for *Vibrio*. The content of NaCl in alkaline peptone water is not standardized, but is usually 0.5 to 1%. It can be increased to 2% to allow better growth of the marine vibrios. If no NaCl is added, it becomes much more selective for *V. cholerae* and *V. mimicus* (see alkaline peptone water—saltless). The type of peptone used in the medium has also varied depending on several factors including local availability. The formula given below is the one used in our laboratory for many years. Other formulations are probably equally effective, but we have no experience with them.

CDC Medium 1494

Peptone (Bacto)	10 g
Sodium chloride	5 g
Water	994 ml
Sodium hydroxide, 1 N (see below)	

Dissolve the peptone and sodium chloride in the water. Insert a pH electrode and add 1N NaOH dropwise until the pH has risen to 8.4; about 6 ml will be required. Dispense and autoclave at 121°C for 15 min. The final medium will be clear and amber colored.

Isolation—Clinical Specimens

Laboratory Routine for *Vibrio* Work

Many of the techniques used in clinical microbiology and enteric bacteriology laboratories work well with the genus *Vibrio*. However, there are some specialized items that are recommended for laboratories that often isolate and identify *Vibrio* species (Barua and Burrows, 1974; Benenson et al., 1964; Hugh and Sakazaki, 1972; Morris et al., 1979; Wachsmuth, 1984; World Health Organization, 1983) and for clinical laboratories that want to increase their capability. Two factors can complicate the isolation and identification of *Vibrio*. Sometimes *Vibrio* cultures will not grow well on the highly selective media used to isolate “enteric pathogens.” The other factor is that the halophilic species of *Vibrio* need added NaCl for optimum growth and activity (Baumann and Schubert, 1984), and several common laboratory media have suboptimum amounts of Na⁺ (less than 0.5% NaCl). Solutions to these problems are discussed below.

Collection, Transport, and Storage of Specimens

EXTRAIESTINAL SPECIMENS The usual procedure for collecting and processing these speci-

men (blood, wound, tissue, etc.) is followed. There are no special procedures for *Vibrio*.

STOOL SPECIMENS Stool specimens should be collected early, preferably within the first 24 hours of illness, and before the patient has received any antimicrobial agents.

TRANSPORT Whenever possible, stool or rectal swab specimens should be inoculated on isolation plates with minimal delay. Viability of *Vibrio* species is well maintained at the alkaline pH of typical feces from cholera patients’ rice-water stools, but is unpredictable in formed stools. *Vibrios* are very susceptible to desiccation, so specimens must not be allowed to dry.

When there will be a delay in plating a culture (especially when it must be transported by courier), rectal swabs or fecal material should be placed in alkaline peptone water or into Cary and Blair semisolid transport medium, which maintains viability of *Vibrio* cultures for up to 4 weeks. Buffered glycerol-saline, often used in enteric bacteriology, is an unsatisfactory transport medium even for short periods. Tellurite-taurocholate-peptone broth has been extensively used with success as an “enrichment transport” medium at the International Center for Diarrheal Diseases Research in Dhaka, Bangladesh, where specimens collected in the field are generally plated within 12 to 24 hours. In the absence of available suitable transport media, strips of blotting paper may be soaked in liquid stool and inserted into airtight plastic bags. Specimens collected in this way may remain viable for up to 5 weeks.

STORAGE AND SHIPMENT Specimens in transport media may be shipped to the laboratory without refrigeration, but all normal precautions and shipping regulation must be followed.

Overall Plan for Isolation

Table 5 gives four different approaches to the isolation of *Vibrio*. The approach adopted by a particular laboratory will probably depend on the frequency with which *Vibrio* cultures are encountered. The routine use of TCBS medium brings immediate attention to a possible *Vibrio* isolate, but its routine use is not cost effective. In an 18-month study, M. T. Kelly (see Farmer et al., 1985) found that every *Vibrio* isolated from TCBS medium was also detected on other plating media which were screened for oxidase-positive colonies. Other negative factors include the fact that different lots of commercial TCBS medium vary in their selectivity, and some species or strains of *Vibrio* do not grow well on TCBS.

Figure 6 gives an overall plan for using special methods to enhance the *Vibrio* isolation rate. One simple procedure will probably result in a higher isolation rate for *Vibrio*. Hemolytic colonies on sheep blood agar plates can be tested for their oxidase reaction, which will detect strongly hemolytic colonies of *Aeromonas* and some *Vibrio* species. This will also detect some weakly hemolytic *Vibrio* and *Plesiomonas* cultures. Oxidase testing can also be done on non-hemolytic colonies (see below). A latex agglutination test (Fig. 6) can be useful as a rapid screening method for detecting *V. cholerae* but a positive culture is always required for the definitive diagnosis of cholera.

EXTRAINTESTINAL SPECIMENS These are usually processed with no particular attention to *Vibrio*. The *Vibrio* species of medical importance grow well on blood agar and many also grow on MacConkey agar. On blood agar strains of *V. cholerae* have a characteristic morphology (Fig. 7) and are usually strongly hemolytic (except for the classical biogroup). However, a more thorough search for *Vibrio* isolates can be done with

oxidase testing or by including a plate of TCBS medium.

STOOL SPECIMENS Cultures of *Vibrio* will grow well on blood agar (Fig. 8) where they may either be: beta-hemolytic (*V. cholerae* non-O1, and some *V. cholerae* O1 strains of the eltor biotype), alpha-hemolytic *V. vulnificus* and many others), or non-hemolytic. They usually grow on MacConkey agar (sometimes with a reduced plating efficiency) and will appear as colorless (lactose-

Fig. 7. Strong hemolytic reaction of the Gulf Coast strain of *Vibrio cholerae* on sheep blood agar plates (overnight incubation at 36°C); note that the small colony type has a much larger zone of hemolysis than the large colony type.

Table 5. Four approaches for the isolation of *Vibrio* cultures from clinical specimens.

1. Use normal procedures and make no special effort to search for *Vibrio*.
2. Use normal procedures and look for oxidase-positive colonies on plating media, especially on blood agar.
3. Incorporate TCBS agar as an extra plate for stool cultures, and also for other likely specimens such as wounds, blood, eye, and ear.
4. Use other special media and procedures to enhance the isolation of *V. cholerae*, *V. parahaemolyticus*, and other *Vibrio* species.

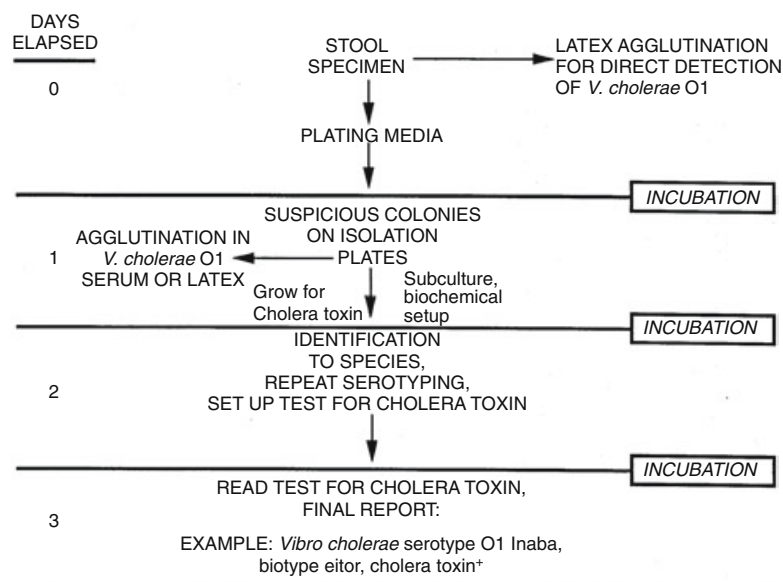

Fig. 6. Overall plan and special methods for the isolation and identification of *Vibrio cholerae* and other *Vibrio* cultures.

Fig. 8. Variation in the size and shape of *Vibrio cholerae* cells taken directly from cholera patients and laboratory cultures as reported by Robert Koch in 1883; note the curved rods that led Koch to use the name "comma bacillus." (a) Intestinal content of a cholera patient. (b) Rice-water stool of a cholera patient after 2 days incubation on moist clothing. (c) Growth from meat-broth laboratory culture (note long spiral forms). (All redrawn from Koch's original figures as reproduced on p. 100 of Pollitzer, 1959.)

negative) colonies. Oxidase testing can be done on colonies grown on blood agar and on lactose-negative colonies on selective media; however, lactose-positive colonies from selective media can give false-negative oxidase reaction. *Vibrio* cultures often do not grow well on the more selective enteric plating media.

Oxidase Testing of Colonies from Primary Plates

This appears to be a cost-efficient method for the detection of *Vibrio* cultures without having to add an additional plating medium such as TCBS agar.

Oxidase Tests

Method 1. An isolated colony on a blood agar plate is touched and spot tested for oxidase reaction by Kovacs' method. A total of 50 to 10 colonies are tested.

Method 2. Growth from a crowded area is taken up with a cotton swab and smeared onto the filter paper soaked with Kovacs' oxidase reagent.

Method 3. A drop of Kovacs' oxidase reagent is added to an area of the blood agar plate where the colonies are crowded but still separated. The drop should cover 50 to 100 colonies. Oxidase-positive colonies turn purple within 1 minute.

If oxidase-positive colonies are present in methods 2 or 3, individual isolated colonies (not previously touched or exposed to the reagent) from an area of less crowding are tested for their oxidase reactions as described in method 1. Since most specimens will have no oxidase-positive colonies (other than *Pseudomonas aeruginosa*), this method reduces the number of colonies which require individual screening. Oxidase-positive colonies (other than *P. aeruginosa*) detected by the above method are then identified to species. This method has another advantage because it also detects cultures of *Aeromonas* and *Plesiomonas*. Oxidase testing should improve the isolation rate, but it may not be very cost effective in some geographical locations because of low yields of *Vibrio*, *Plesiomonas*, and *Aeromonas*.

Specialized Media and Methods for *Vibrio* Isolation

USE OF TCBS AGAR The advantage of using TCBS agar is that it increases the laboratory worker's awareness of suspect *Vibrio* colonies, and usually results in an increased number of isolates. Many laboratories near oceans or salty areas use TCBS agar as a plating medium for stool and other specimens (Bonner et al., 1983). It is recommended as the single best medium to detect *Vibrio* from human clinical specimens. Table 4 gives some information about the growth of the *Vibrio* species on TCBS agar. This medium is particularly useful for isolating *V. cholerae* or *V. parahaemolyticus* from feces. There is considerable variability in the selectivity of TCBS from different manufacturers and quality control of each new lot is essential.

SPECIAL EFFORTS TO ISOLATE *VIBRIO CHOLERA*E AND OTHER *VIBRIO* SPECIES FROM FECES Fig. 6 is a schema adapted from Wachsmuth et al. (Wachsmuth et al., 1980) and Furniss et al. (Furniss et al., 1978) for the isolation of *V. cholerae* from feces. It should also be useful in isolating other *Vibrio* cultures from feces and other specimens. TCBS agar and enrichment in alkaline peptone water select for *Vibrio* species. The main disadvantage of this approach is that these methods are in addition to the usual laboratory routine, and may cause much additional work with a poor yield of specimens positive for *Vibrio*.

MICROSCOPIC EXAMINATION OF GROWTH In 1883, Koch noted the appearance of small curved rods in the rice-water stools of cholera patients (Fig. 8). These typical curved rods were not seen in feces of patients without cholera. A number of

Fig. 9. Cellular morphology of *Vibrio cholerae*, *V. parahaemolyticus*, and *V. alginolyticus*. (a) *V. cholerae* from an 18-h culture on nutrient agar (Van Ermengen cilia stain). (b) Flagella stain of *V. parahaemolyticus*. (c) Electron micrograph of *V. parahaemolyticus*; note single-sheathed polar flagellum. (d) Electron micrograph of *V. alginolyticus* grown on solid media; peritrichous flagella are present; note their different size and shape as compared to the sheathed polar flagellum. (From Farmer et al., 1985.)

other authors have made the same observation and commented on the possible usefulness of this observation. *Vibrio cholerae* has considerable variability in its cellular morphology (Fig. 8), which includes typical curved rods, straight rods, short noncurved rods, and “involution forms” (Fig. 8C). Often these can all be seen in the same culture. For this reason, microscopic examination of feces or of cultures does not have a prominent role today. However, the finding of typical curved forms can be used as presumptive evidence for the presence of *Vibrio*. *Vibrio* cultures grown in liquid media have polar flagella, but many strains have peritrichous flagella when grown on solid media (Fig. 9). However, flagella stains are impractical for routine identification.

Isolation—Marine and Environmental Samples

Enrichment Cultures (from Baumann and Baumann, 1981)

Most enrichment cultures are incubated at room temperature (18–22°C), while cultures on petri plates are incubated at ambient temperature or 25°C. These temperatures are primarily a matter of convenience and can be modified (usually reduced, as in the case of the luminous bacteria) to suit the particular needs of the investigator.

Carbon sources are added to enrichments at a concentration of 0.1–0.2% (w/v for solids and v/v for liquids). For the cultivation of amino acid-requiring organisms, basal medium (medium “BM” of Baumann and Baumann, 1981) is supplemented with 1 mg/liter each of L-alanine,

L-arginine, L-asparagine, L-aspartate, L-cysteine, L-glutamate, L-glutamine, glycine, L-histidine, L-isoleucine, L-leucine, L-lysine, L-methionine, L-phenylalanine, L-proline, L-serine, L-threonine, L-tryptophan, L-tyrosine, and L-valine. The amino acids are filter-sterilized and added to the autoclaved medium.

The carbon—energy source (unless labile or volatile) is added to the double-strength medium BM prior to autoclaving. Filter-sterilized labile or volatile compounds are added to the basal medium with added agar (medium BMA of Baumann and Baumann, 1981), which has been cooled to about 41°C prior to the pouring of plates. Some volatile substrates (geraniol, *n*-hexadecane, naphthalene, and phenol) are not added to the medium but are placed on sterile filter paper in the lids of the inverted petri dishes, then incubated in air-tight containers. It should be stressed that the medium of MacLeod based in artificial seawater (1968) may not be suitable for growing some marine organisms that may require additional mineral components. A number of different artificial seawater formulations have been compiled by Kinne (1976). Although many marine bacteria are not adversely affected by Tris buffer, the compound may prove toxic for some strains.

BM Medium (Basal Medium of Baumann and Baumann, 1981)

Tris HCl (pH 7.5) (see below)	15.8 g (100 mM)*
Ammonium chloride (NH ₄ Cl)	1 g (19 mM)
Potassium phosphate (K ₂ HPO ₄ · 3H ₂ O)	57 mg (0.33 mM)
Ferrous sulfate (FeSO ₄ · 7H ₂ O)	28 mg (0.1 mM)
Water	500 ml

Artificial seawater (MacLeod formula) 500 ml
(see "Isolation," this chapter)

Or use 7.9 grams for 50 mM (Baumann and Baumann, 1981)

BMA Medium (Basal Medium Agar of Baumann and Baumann, 1981)

Prepare 500 ml double-strength BM medium, add the carbon source (if it can withstand autoclaving), autoclave, and cool. If the carbon source is heat labile, filter-sterilize and add aseptically to cooled BM medium. Prepare 500 ml of a double-strength agar solution (40 g refined agar per liter), autoclave, and cool. Mix the BM plus carbon source with the agar solution and pour onto plates.

Isolation from Seawater (Baumann and Baumann, 1981)

It is essential that seawater be collected aseptically using sterile samplers. In general, this presents little difficulty when samples of surface waters are collected. A convenient way of obtaining seawater from different depths is by use of the Niskin butterfly sampler (General Oceanics, Miami, FL, USA). The collected samples can be used either for enrichment cultures or for direct isolation.

DIRECT ISOLATION Samples of seawater (5–300 ml) are filtered through 0.22- or 0.45- μ m nitrocellulose filters which are placed on petri plates containing either a complex medium (marine agar or a similar nonselective medium) or BMA medium with 0.1% of the carbon and energy source. The size of the filtered sample will depend on the source of the seawater and the composition of the medium used for direct isolation. After an incubation of 2–10 days at 25°C, colonies are picked and restreaked on homologous media. *V. nigripulchritudo* can be frequently obtained by direct isolation on plates containing BMA with 0.2% lactose, which will also often yield *Alteromonas macleodii*.

Many agar decomposers produced a broad but barely perceptible indentation in the agar surrounding the colony. Consequently, it is advisable to streak a pure culture on BMA medium without an added carbon and energy source and containing appropriate supplements for growth-factor-requiring organisms. Growth on this medium indicates that the isolate is able to utilize agar. Organisms in the marine environment apparently do not utilize Tris buffer as a carbon and energy source, although some organisms appear to utilize this compound as a poor nitrogen source.

ENRICHMENT CULTURES For aerobic enrichments, 500 ml of seawater is added to a sterile 2-liter Erlenmeyer flask containing 25 ml of 1 M

Fig. 10. Colonial morphology of *Vibrio nigripulchritudo*; note the granules of blue-black pigment embedded in the colonies. (From Baumann and Baumann, 1981.)

Tris-HCl (pH 7.5), 0.5 g NH_4Cl , 38 mg $\text{K}_2\text{HPO}_4 \cdot 3\text{H}_2\text{O}$, 14 mg $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, and 0.5–1.0 g of the carbon and energy source (acidic or basic carbon sources may require readjustment of the pH to 7.5). Depending on the source of the sample and the organic compound used to support growth, both the sample volume and the volume of the concentrated solution may be increased or decreased. The flasks are observed for signs of growth for up to 10 days, and then they are streaked on BMA medium containing 0.1% of the same carbon and energy source as was used in the enrichment. Enrichments containing 0.2% chitin, incubated aerobically for 5–10 days, often contain a blue-black sediment associated with the chitin particles. Such enrichments, when streaked on medium BMA containing 0.2% lactose, usually yield *V. nigripulchritudo*, a chitin-decomposer which forms colonies containing crystals of blue-black pigment (Fig. 10) (Baumann et al., 1971b). *V. alginolyticus* can be readily obtained from aerobic enrichments containing 0.5% yeast extract and 0.5% tryptone (instead of the single organic carbon and energy source). When streaked on marine agar or a similar medium, this organism swarms in a manner similar to that of *Proteus*. Single colonies can be obtained by streaking on either a complex medium containing 4% agar or on minimal medium such as BMA with 0.2% glycerol.

ISOLATION FROM SURFACES AND INTESTINAL CONTENTS OF FISH Sterile cotton-tipped applicator sticks are used to swab the gills, mouth, and rectal region as well as other surfaces of the fish. An agar plate is then streaked to give isolated colonies. A 2–3 cm portion of the fish intestine is dissected and placed onto a sterile petri plate. Gentle pressure with sterile forceps or an applicator stick generally forces out some of the intestinal contents, which are streaked on plating medium. In both cases the plates are

incubated for 1–4 days and observed for colonies, which are then purified by streaking on homologous medium. Some marine strains swarm extensively on complex media making it impossible to isolate single colonies. Swarming can be prevented by raising the concentration of agar to 4%.

Isolation of Bioluminescent Bacteria (Baumann and Baumann, 1981)

These organisms are common in the marine environment. The detection of luminescence by a simple visual examination poses a number of problems since the intensity of the emitted light varies greatly with different isolates and is also affected by the cultivation medium as well as by the age of the cells. A satisfactory medium used for the observation of luminescence is LM medium (Baumann and Baumann, 1981). Strains are streaked on this medium and incubated at 15°C and 25°C with periodic examinations at 12–36 h after streaking. In many strains, luminescence is relatively dim and short-lived so that frequent observation (every 3 h) is suggested. It is important to have plates with isolated colonies since, in the case of many dim strains, only the isolated colonies luminesce. Examination for luminous colonies on plates containing LM medium should be done in complete darkness, and the eyes should be dark-adapted for at least 10 min. The picking of luminous colonies is greatly facilitated by the use of sterile toothpicks and a low-intensity light bulb (5–10 watts) connected to a rheostat (Cosenza and Buck, 1966). First, in total darkness, an area of luminescence is observed, and a sterile toothpick is positioned roughly over the site. The current is then switched on and the intensity of the light is gradually increased until the specimen is just barely visible. By fixing one's eyes on the luminous spot and gradually increasing the intensity of the light it becomes apparent which area contains the luminous organisms. The toothpick is quickly touched to this site; a plate of LM medium is inoculated; and the light is quickly turned off. By using this procedure, the investigator's eyes do not have to be repeatedly dark-adapted and, more importantly, it is possible to actually see the area from which the inoculum is picked.

LM Medium (Luminous Medium of Baumann and Baumann, 1981)

Tris HCl (pH 7.5)	7.9 g (50 mM)
Yeast extract	5 g
Tryptone	5 g
Calcium carbonate (CaCO ₃)	1 g
Agar	20 g
Glycerol	3 g
BM medium	1 liter

ISOLATION FROM SEAWATER In some coastal waters, the concentration of luminous bacteria may be sufficient to allow detection in a 0.1 to 1-ml sample spread onto a plate of LM medium, TCBS medium, or marine agar. With larger volumes of seawater, aliquots of up to 300 ml may be filtered through 0.22 or 0.45-μm nitrocellulose filters which are subsequently placed onto petri plates containing one or more of these media. Since crowded conditions tend to inhibit luminescence and since nonluminous bacteria greatly outnumber the luminous isolates, it is important that the filter contain a relatively sparse bacterial population. It is not recommended that the soft agar overlay method be used for the enumeration of luminous bacteria since brief exposure to 41°C (the temperature of the molten agar used for the overlay) may kill some strains of *Photobacterium phosphoreum* and *V. logei*.

ISOLATION FROM SURFACES AND INTESTINAL CONTENTS Fresh squid and octopus, which have been kept on ice in fish markets, often have luminous spots when examined in the dark; however, luminous spots are rare on fresh fish. The isolation of luminous organisms from such specimens, from the surfaces of marine animals, as well as from the intestinal contents of fish, is done as described above. In general, the intestinal contents of fish have either a relatively large population of luminous bacteria or none (Baumann and Baumann, 1981).

ISOLATION BY ENRICHMENT This procedure is given in Baumann and Baumann (1981) and based on some suggestions of M. Doudoroff. In some cases, visible regions of luminescence can be obtained on fresh fish, squid, or octopus by half-submerging the specimen in a shallow layer of artificial seawater and incubating for 10–18 h at 12–15°C. The luminous sites are touched with sterile toothpicks and inoculated onto plates of LM medium or other media as previously described. This method is relatively specific for *P. phosphoreum*.

Stock Cultures and Methods for Preservation

In the Vibrio Laboratory at CDC, a “permanent frozen stock” is made by suspending growth from a blood agar or marine agar plate in skim milk (10%) which is transferred to a plastic vial and frozen and stored at –70°C. A “working stock” is also prepared. *V. cholerae*, *V. mimicus*, and other nonhalophilic species are grown in screw-cap tubes of working-stock media; halophilic vibrios are grown in marine semisolid medium (marine broth with 0.3% agar added). After the strain has grown well (usually 24 h) a

thin layer of sterile mineral oil is added to cover the top of the agar column to prevent evaporation and drying. We do not transfer these working cultures. The occasional strain that dies is replaced from the permanent frozen stock. Tubes are stored in divided boxes at room temperature in the dark. Do not store stock cultures in the refrigerator because this kills many strains. The only exception is for strains that do not grow well above 20°C; they are stored in the refrigerator. Some isolates of *Vibrio* acquire nutritional requirements after prolonged cultivation and frequent transfer on marine agar. Baumann and Baumann (1981) suggest maintaining strains on medium BMA containing 0.2% glycerol or freeze-drying them.

Most of the strains of *Vibrio* can be freeze-dried and kept at 4°C. With a few exceptions, viable cells could be recovered after 3–5 years of storage. For the preparation of lyophils, the growth from a fresh slant is suspended in about 0.5 ml of a sterile solution consisting of one-quarter-strength artificial sea water #1 (MacLeod's formula), 5 g/liter yeast extract, and 5 g/liter peptone (adjusted to pH 7.5), and transferred into a lyophil tube which is subsequently placed in a mixture of dry ice and acetone and placed under vacuum for 10–12 hrs. The lyophils are reconstituted by suspending the powder in about 0.5 ml of an optimum growth medium and inoculating a solid medium. Growth is generally observed after 1–2 days of incubation at 25°C. For *P. phosphoreum*, a lower temperature (15–18°C) should be used.

Identification—Clinical Isolates

Because of the varying pathogenicity and clinical significance of the different species, *Vibrio* strains isolated from clinical specimens should be identified to species. There are many different approaches to identification (for a review, see Farmer et al., 1981). One common question always needs an immediate answer: "Is the *Vibrio*-like organism isolated from this particular case of cholera-like diarrhea the pandemic strain of *V. cholerae*?" (Fig. 6).

Ruling Out *V. Cholerae* Serogroup O1

It is often important to give a definitive answer to this question as quickly as possible. Numerous sucrose-positive (yellow colonies) on TCBS agar from a patient with rice-water stools or severe watery diarrhea warns of the possible presence of *V. cholerae* serogroup O1 (Fig. 11). Suspicious colonies are subcultured early in the day by heavy inoculation on a nonselective medium such as blood agar or trypticase soy agar which

Fig. 11. Colonies of *Vibrio cholerae* on TCBS agar; yellow colonies of 2- to 3-mm diameter are present after overnight incubation at 36°C.

does not contain carbohydrates. After 5–8 h, good growth should be present which can be tested in polyvalent antisera to *V. cholerae* serogroup O1 (Fig. 6). Experienced workers use growth from the primary TCBS plate to do the agglutination. Positive agglutination is presumptive evidence of *V. cholerae* serogroup O1, and the result should be reported immediately to the physician. Biochemical testing is necessary to confirm the identification as *V. cholerae*. Local health authorities should be notified immediately, and the culture, along with information about the case, should be forwarded to the state health laboratory.

DIRECT TESTING OF LIQUID STOOLS FOR *V. CHOLERA*
O1 Jesudason et al. (1984) in India showed that there was enough O antigen in rice-water stools of cholera patients to agglutinate a reagent consisting of *Staphylococcus aureus* cells coated with antibodies to the O1 antigen. Shaffer et al. (1989) used a commercial reagent (monoclonal antibodies to serofactor "a" of the O1 antigen coated onto latex particles) for the laboratory diagnosis of cholera in the field. If sufficient O antigen is present in the liquid stool, it will cause the latex to clump (Fig. 12); this is a presumptive positive for *V. cholerae* O1. This method is particularly suited for field testing (Fig. 13) in developing countries where laboratory facilities for bacteriological analysis are usually unavailable. False negatives and false positives can occur with these two methods, so a positive culture is always needed for the definitive diagnosis of cholera.

Biochemical Identification

EFFECT OF MEDIA, REAGENTS, AND Na⁺ CONCENTRATION Most laboratories identify *Vibrio* strains with media and tests designed to identify Enterobacteriaceae. These work well for *V. cholerae* and *V. mimicus* because they have only a low requirement for Na⁺, which is fulfilled

Fig. 12. Identification of *Vibrio cholerae* serotype O1 with a commercial latex reagent; two strong positive reactions are on the left, and two negative ones on the right.

Fig. 13. Laboratory diagnosis of cholera in the field using a commercial latex reagent.

by the amount of NaCl in the medium. However, most of the halophilic vibrios require much more Na⁺ for growth and expression of various metabolic pathways. Some of the media for differential biochemical tests do not contain enough NaCl for these halophilic species. In Table 1, the standard enteric test is listed first and the percentage positive for each species is given. The percentage positive for each species is then given for a modified medium with 1% NaCl added. The table also shows that more *Vibrio* species are indole positive when the medium is changed from peptone water to heart infusion broth. More strains are Voges-Proskauer positive

when the reagent for detecting acetylmethylcarbinol contains alpha-naphthol (Berrit method). This table illustrates the pronounced effect of media and methods on the results of biochemical tests.

SCREENING AND TESTS AND COMPLETE IDENTIFICATION Table 6 gives the tests that are most helpful in dividing the 12 species of *Vibrio* that are found in clinical specimens into 6 groups; Table 7 gives the complete biochemical reactions for these 12 species. The vast majority of *Vibrio* cultures isolated from clinical specimens will be easily identified as one of the 12 species listed. Growth in the absence of added Na⁺ (growth in nutrient broth with 1% NaCl, but no growth in nutrient broth) is the essential test for differentiating *V. cholerae* and *V. mimicus* from the other 10 species of *Vibrio* and from the marine vibrios. *V. metschnikovii* is easily differentiated because it is oxidase negative and nitrate negative. *V. cincinnatiensis* is easily differentiated because it is inositol positive. *V. hollisae* is negative for arginine dihydrolase and for lysine and ornithine decarboxylases (triple decarboxylase negative), which differentiates it from the remaining *Vibrio* species (Table 6). The remaining seven species are subdivided into the "arginine-dihydrolase-positive group," which includes *V. damsela*, *V. fluvialis*, and *V. furnissii*; and into the "lysine-decarboxylase-positive group," which includes *V. alginolyticus*, *V. parahaemolyticus*, *V. vulnificus*, and *V. carchariae* (Table 6). The tests that are most useful for further differentiating the 12 clinical species are given in Tables 7 to 14. Several of these media and tests are specialized for vibrios and will be described in more detail later.

COMPUTER IDENTIFICATION We have developed several computer programs that have proved useful in the routine identification of *Vibrio* and *Photobacterium* isolates. The programs are based on mathematical analysis of the results of the

Table 8. Key characteristics of *Vibrio cholerae* and *V. mimicus* and tests for their differentiation.^a

Test or property	<i>V. cholerae</i>	<i>V. mimicus</i>
Frequency of isolation	Very common	Occasional
Properties of both species:		
Oxidase	+	+
Growth in nutrient broth with:		
No added NaCl	+	+
1% NaCl	+	+
Lysine decarboxylase	+	+
Arginine dihydrolase	–	–
Ornithine decarboxylase	+	+
Differentiation of the species:		
Sucrose fermentation	99 ^b	0
Lipase (corn oil)	95	10
Voges-Proskauer	95 ^c	0
Lactose fermentation (1–2 days)	9	74
Lactose fermentation (3–7 days)	24	56

^aAll data are for reactions within 2 days at 35–37°C unless otherwise specified. Symbols: +, 90 to 100% positive; –, 0 to 10% positive.

^bEach number gives the percentage of positive reactions after 24 to 48 h of incubation at 35–37°C (unless another temperature or time is indicated). Most of the positive reactions occur during the first 24 h of incubation.

^cAlmost all strains of *V. cholerae* non-O1 and most strains of *V. cholerae* O1 currently isolated are of the eltor biogroup, which is almost always Voges-Proskauer positive; the classical biogroup is Voges-Proskauer negative.

Table 9. Differentiation and properties of the classical and eltor biogroups of *V. cholerae* serogroup O1.^a

Test or property	Biogroup	
	Classical	Eltor
Frequency of isolation:		
On the Indian subcontinent	Occasional ^b	Common
In the rest of the world	Very rare	Common
Differential test:		
Hemolysis of red blood cells	–	+
Voges-Proskauer	–	+
Inhibition by polymyxin B (50-unit disk)	+	–
Agglutination of chicken red blood cells	–	+
Lysis by bacteriophage:		
Classical IV	+	–
FK	+	–
Eltor 5	–	+

^aSymbols: +, most strains (generally about 90 to 100%) positive; –, most strains negative (generally about 0 to 10% positive).

^bThe classical biotype reappeared several years ago on the Indian subcontinent and has been found only in some locations.

Table 10. Antigenic serofactors of *Vibrio cholerae* O1: subtypes Ogawa, Inaba, and Hikojima.

Serotype O1 subtype	O factors present in culture	Agglutination in absorbed serum:	
		Ogawa ^a	Inaba ^a
Ogawa	A, B	+	–
Inaba	A, C	–	+
Hikojima ^b	A, B, C	+	+

^aThe specific factor sera are prepared by absorption. For example, an Ogawa antiserum is prepared by injecting an Ogawa culture, and then absorbing the resulting antiserum with an Inaba culture, which removes the antibodies to O antigen factor A, leaving antibodies to O factor B.

^bSome authorities do not recognize subtype Hikojima, and report these cultures as either Inaba or Ogawa, based on which serum causes the quickest and strongest agglutination.

Table 11. Subdivision of *Vibrio cholerae* below the level of species.

^aAll data are for reactions within 2 days at 35–37°C unless otherwise specified. Symbols: +, 90 to 100% positive; (+), 75 to 89.9% positive; (–), 10.1 to 25% positive; –, 0 to 10% positive.

simple biochemical tests given in Table 15. The biochemical test media are inoculated, read at days 1 and 2 (and up to seven days if desired). Each test result is coded as “+” or “-” for the computer, which then compares the profile of the unknown strain to all the organisms in the data base. The approach is based on the normalized likelihood calculation described by Lapage 1974. Two different programs are used: the first, named “George,” is for all species of Enterobacteriaceae and for the species of *Vibrio* that grow well at 35–37°C in media with no added salt (0.5–1.0% NaCl). A second program named “Neptune” was designed specifically to identify the halophilic species of *Vibrio* and *Photobacterium*. The biochemical tests used in this program have marine cations added (Table 15) to give a higher content of Na⁺, K⁺, and Mg⁺⁺, and all incubations are done at 25°C since many of the species do not grow well at 35–37°C. Both programs are useful in comparing an unknown to a large data base of species, biogroups, and individual strains. The programs originally were run on a main-frame computer, but we have modified them to run on IBM-compatible microcomputers with DOS. They may be obtained by writing J. J. Farmer.

Bioluminescence Test

This is a useful differential test because a few species are usually bioluminescent (*V. fischeri*, *V. logei*, *V. orientalis*, *V. splendidus* biogroup 1, *Photobacterium phosphorium*, and *P. leiognathi*), in contrast to most of the other species. Some strains of *V. harveyi* are luminescent, as are a scant few strains of *V. cholerae*. None of the members of the Enterobacteriaceae (with the lone exception of *Xenorhabdus luminescens*) and Pasteurellaceae, or of the genera *Aeromonas* and *Plesiomonas* are bioluminescent.

Bioluminescence Test for Vibrios

Inoculate the test strain on a medium or several media that allow good growth, such as marine agar, commercially available *Photobacterium* agar, LM medium, or trypticase soy agar (for organisms that do not require Na⁺), and incubate at 25°C. Also inoculate quality-control strains which are “strong” and “weak” for bioluminescence. After incubation for about 8 h and again at 16–20 h, take the plates into a room that can be totally darkened and set them on a bench top. Take in a flashlight, and turn off the overhead light. Observe the weak and strong quality-control cultures for light. Light from the strong positive culture should be visible within a few seconds, but the weak positive culture may take several minutes. Continue to observe the test culture for luminescence and record as positive or negative after 5 and again at 10 minutes. For quality control, include a strong positive such as *Vibrio fischeri* (or a similar reference culture or marine isolate); also include a weak positive such as *Xenorhabdus luminescens* or a weakly luminescent

marine strain that takes 3–5 min of dark adaptation to be seen. Test as many cultures as possible for bioluminescence at one time because this test is time consuming to set up. A photographic dark room is a good place to do the observation for light emission.

Carbon Assimilation Tests (Baumann and Baumann, 1981)

The medium described below which is used for assimilation tests was described by McLeod (1968) to study the growth of marine bacteria on different substrates, and was subsequently used by Baumann and Baumann (1981). The carbon sources are added to the basal medium at a final concentration of 0.1 to 1% as described in “Isolation—Marine and Environmental Samples.”

Marine Broth

Marine broth is useful for the isolation and cultivation of marine organisms. A dehydrated powder is available from Difco (catalog no. 0791). It uses the following recipe:

Peptone (Bacto)	5 g
Yeast extract	1 g
Ferric citrate	0.1 g
Sodium chloride	19.45 g
Magnesium chloride (dried)	5.9 g
Sodium sulfate	3.24 g
Calcium chloride	1.8 g
Potassium chloride	0.55 g
Sodium bicarbonate	160 mg
Potassium bromide	80 mg
Strontium chloride	34 mg
Boric acid	22 mg
Sodium silicate	4 mg
Sodium fluoride	2.4 mg
Ammonium nitrate	1.6 mg
Disodium phosphate	8 mg
Distilled water	1 liter
Adjust to pH 7.6.	

Add 37.4 g of Difco marine broth to the distilled water and heat to boiling. Dispense into tubes or bottles and autoclave at 121°C for 15 minutes. A brown gelatinous precipitate is produced during autoclaving which settles to the bottom.

Marine Semisolid Medium

This is a convenient semisolid medium for maintaining stock cultures of *Vibrio*, *Photobacterium*, or other marine organisms that require added Na⁺ and other ions for growth.

Marine broth (Difco 0791)	37.4 g
Agar	4 g
Distilled Water	1 liter

Add the marine broth to the water. Add 4 g of agar, and heat to boiling. Dispense 6 ml into 13 × 100 mm screw cap tubes. Tighten the caps and autoclave at 121°C for 15 minutes.

Marine Cations Supplement 1558

This medium is useful for increasing the salt content of bacteriological media to enhance the growth of marine bacteria. It contains Na⁺, K⁺, Mg⁺⁺, and Ca⁺⁺ at 10 times

^aAll data are for reactions that occurred at 1 or 2 days (unless 7 days is specified) in normal enteric media with added marine cations at 25°C (unless 15° is specified). Symbols: +, 90% to 100% positive; (+), 75 to 89.9% positive; V, 25.1 to 74.9% positive; (-), 10.1 to 25% positive; -, 0 to 10% positive.

the in-use concentration. It is our formulation which was modified from the "electrolyte supplement" of Furniss et al. (1978), and it is added in the ratio of one volume of supplement to nine volumes of medium.

Sodium chloride (NaCl)	150 g
Potassium chloride (KCl)	3.7 g
Magnesium chloride ($\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$)	51 g
Calcium chloride ($\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$)	7.4 g
Water	912 ml

Dissolve the ingredients in the order listed. All should dissolve readily, and a crystal-clear, colorless solution should result. The volume of the solution will expand to 1 liter after the salts dissolve. Dispense and autoclave at 121°C for 15 minutes. It should remain crystal clear after autoclaving, but a slight amount of fine precipitate may form and settle to the bottom of the container. To use this supplement in other media: aseptically add one volume of marine cations, supplement 1558 to nine volumes of the sterile medium, and mix thoroughly.

Marine Cations Supplement 1559

This medium is the same as marine cations supplement 1558 except that it lacks the calcium chloride. It contains Na^+ , K^+ , and Mg^{++} at 10 times the in-use concentration. This avoids precipitates, which are often produced when media containing supplement 1558 are autoclaved.

Sodium chloride (NaCl)	150 g
Potassium chloride (KCl)	3.7 g
Magnesium chloride ($\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$)	51 g
Water	912 ml

Dissolve the ingredients in the order listed. All should dissolve readily, and a crystal-clear, colorless solution should result. The volume of the solution will expand to 1 liter as the salts dissolve. Dispense and autoclave at 121°C for 15 minutes. A crystal clear solution should result after autoclaving, but a slight amount of fine precipitate may form and settle to the bottom of the container.

To use this supplement in other media: aseptically add one volume of marine cation supplement 1559 to nine volumes of the sterile medium, and mix thoroughly.

Susceptibility to the Vibriostatic Compound O129

This test of susceptibility to O129 (2,4-diamino-6,7-diisopropyl-pteridine phosphate) was originally used to differentiate cultures of *Vibrio* (usually susceptible) from *Aeromonas* (very resistant), but the test has differential value in the family Enterobacteriaceae, and can also be used to differentiate cultures of the family Pasteurellaceae from Enterobacteriaceae (Chatelain et al., 1979). Table 16 gives the susceptibility of three families.

Almost all methods for testing O129 susceptibility use paper disks that have been soaked in the compound. Originally the disks had to be prepared in the laboratory (Furniss et al., 1978), but now commercial disks are available (see below). Several different methods have been used to measure O129 susceptibility, but the method used by the Maidstone *Vibrio* Laboratory in England (Furniss et al., 1978) is used in many laboratories.

Commercial O129 disks contain 10 µg or 150 µg per disk and can be ordered from Oxoid. They should be stored in the refrigerator.

Test method: Grow the organism and dilute the turbidity until it is the same as a McFarland 0.5 standard. Insert

Table 16. Susceptibility of Enterobacteriaceae, Vibrionaceae, and Pasteurellaceae to the compound O129 (2,4-diamino-6,7-diisopropyl-pteridine phosphate).

Organism	O129 Susceptibility
Family Vibrionaceae	
<i>Vibrio</i> —many species	Very susceptible
<i>Vibrio</i> —some species	Somewhat susceptible
<i>Aeromonas</i>	Very resistant
Family Enterobacteriaceae	
<i>Edwardsiella</i>	Susceptible
Other genera	Resistant
Family Pasteurellaceae	
<i>Pasteurella</i>	Susceptible
<i>Actinobacillus</i>	Susceptible

a cotton swab into the liquid, then wring out as much as possible on the side of the tube. Streak the swab onto a nutrient agar * or trypticase soy agar (used in our laboratory) plate in three directions. Apply 10- and 150-µg O129 disks and incubate overnight. Observe for a zone of inhibition and record the zone size to the nearest mm. Interpret as follows: sensitive, a zone around each disk; partially sensitive, a zone around the 150-µg disk but no zone around the 10-µg disk; resistant, no zone around either disk.

Salt (Na^+) Requirement and Tolerance Tests

These are useful tests for differentiating species of *Vibrio* and *Photobacterium*. Growth in 0% NaCl is an important characteristic that differentiates *Vibrio cholerae* and *V. mimicus* from the halophilic *Vibrio* species. This test has been done by many different methods, which helps to explain why published results vary among laboratories. We use the following procedure in our laboratory:

Salt Requirement and Tolerance Test

Grow the organisms on marine agar for 18–24 hours at 36°C (if it does not grow at 36°C, use 25°C; if it does not grow at 25°C, use 15°C). Remove some growth with a cotton swab and suspend it in nutrient broth (no added NaCl) until the turbidity is the same as a MacFarland 0.5 standard. A recipe for nutrient broth + 0.1% NaCl is given below. Immediately inoculate each of the media listed below with 0.02–0.03 ml (one drop from a disposable pasteur pipette). Incubate overnight and read for visible growth.

Salt (Na^+) requirement media:

Nutrient broth + 0% NaCl
 Nutrient broth + 0.1% NaCl
 Nutrient broth + 0.2% NaCl
 Nutrient broth + 0.3% NaCl
 Nutrient broth + 0.4% NaCl
 Nutrient broth + 0.5% NaCl
 Nutrient broth + 1% NaCl
 Nutrient broth + 2% NaCl
 Marine broth

Salt tolerance media:

Nutrient broth + 6% NaCl

Nutrient broth + 8% NaCl
 Nutrient broth + 10% NaCl
 Nutrient broth + 12% NaCl

Interpret as follows: If the organism has no Na⁺ requirement (or a very small one) it will grow in nutrient broth plus 0% NaCl. If it has a Na⁺ requirement, it will not grow in 0% NaCl, but will grow with the added NaCl or in the marine broth. For each organism the minimum and maximum concentration of NaCl can be determined.

Nutrient Broth + 0.1% NaCl

This is a formula for one of the media mentioned above. It is essential to use a commercial formulation for nutrient broth (Difco, BBL, etc.) that does not contain NaCl; some formulas (for example, Oxoid) have NaCl as an ingredient. Nutrient broth with other concentrations of NaCl are prepared similarly.

Nutrient broth (Difco or BBL)	8 g
Sodium chloride solution, 10%	10 ml
Water	990 ml

Dissolve the nutrient broth in the water and add the 10% sodium chloride solution. Dispense 10 ml into screw-cap test tubes, replace the caps and *tighten them* to prevent evaporation and a resulting change in NaCl concentration. Autoclave at 121°C for 15 minutes. Allow the tubes to cool at room temperature, check each cap to be sure it is tight, discard any tubes that have a loose cap or obvious loss of liquid. It is convenient to dispense the media for salt requirement and tolerance into color-coded tubes. This helps to avoid errors as they are being read.

String Test

The string test has some differential value because many *Vibrio* species (particularly *V. cholerae*) are string-test positive, but many other species, including *Aeromonas*, are negative. Sodium deoxycholate is a detergent that lyses Gram-negative organisms. When cells are lysed, DNA is released into the suspending medium, making it very viscous and able to form “strings of DNA” when touched with a loop that is raised from the surface of the liquid.

Grow the organisms on trypticase soy agar (or marine agar for halophilic species). With a loop, remove some of the growth and make a heavy suspension in one drop (0.1 ml) of a 0.5% sodium deoxycholate solution. Every 10 seconds or so, raise the loop to see if a “string of DNA” has been formed. Interpretation:

Positive result: The solution becomes viscous and a string of DNA is obvious within 60 seconds. (Positive string test = *Vibrio cholerae*.)

Negative result: No string of DNA formed within 60 seconds. (Negative string test = *Aeromonas hydrophila*.)

Sodium Deoxycholate Solution, 0.5%

This reagent is used as the lysing solution for the string test.

Deoxycholic acid, sodium salt (Sigma D6750)	5 g
Water	1 liter

Slowly add the white powder to the water as it is being stirred on a magnetic stirrer. A crystal-clear, colorless solution results.

Serotyping

This technique is usually done by reference or research laboratories rather than by clinical laboratories, and some of the typing schemes that have been described are discussed under the specific organisms. One exception is the use of *V. cholerae* O1 antisera, which can be used in clinical laboratories to test a strain of *V. cholerae* to determine whether it is O1-positive or negative. Simonson and Siebeling (1988) described the use of latex agglutination for the routine identification of several of the *Vibrio* species. Antisera are made to the flagella which is usually species specific, absorbed to latex particles or *Staphylococcus aureus* cells, and then used in a simple slide agglutination test.

Antibiotic Susceptibility

The species of *Vibrio* important in clinical microbiology usually grow well on Mueller-Hinton agar, which is used in the disk susceptibility test. Although Mueller-Hinton agar contains no added NaCl, it contains a hydrochloric acid hydrolysate of casein, which apparently has been neutralized with NaOH and has enough NaCl to allow good growth of the halophilic species of *Vibrio*. However, some of the environmental marine vibrios grow poorly on Mueller-Hinton, presumably because of their higher requirement for Na⁺. Broth dilution susceptibility tests in Mueller-Hinton broth can be done without modification for most *Vibrio* species because the broth contains sufficient Na⁺ (Hollis et al., 1976).

Antibiotic resistance is rare in *Vibrio* compared with Enterobacteriaceae. Table 17 summarizes the results for the strains we have tested. In most cases, resistance appears to be intrinsic to the species rather than acquired through plasmid transfer or through antibiotic exposure. The one exception to this generalization is the antibiotic resistance found in some outbreaks of *V. cholerae*, which have become resistant through the acquisition of R factors. In the United States, strains of *V. cholerae* and other *Vibrio* species have rarely had this type of resistance. Resistance to polymyxin antibiotics (polymyxin B and colistin) can be useful in spotting a culture of the eltor biogroup of *V. cholerae*, or in spotting a culture of *V. vulnificus*. Most other *Vibrio* species are more susceptible.

Identification—Marine And Environmental Isolates

The methods that have been used to identify isolates of *Vibrio* and *Photobacterium* isolated

Table 17. Antibiotic susceptibility (Kirby-Bauer disk method) of 1,025 strains of the *Vibrio* species that occur in human clinical specimens.^a

Antibiotic (zone size range) ^b	Percentage of strains susceptible (number of strains studied)												
	<i>V. cholerae</i> (480)	<i>V. mimicus</i> (75)	<i>V. metschnikovii</i> (22)	<i>V. cincinnatiensis</i> (14)	<i>V. hollisae</i> (34)	<i>V. damsela</i> (21)	<i>V. fluvialis</i> (25)	<i>V. furnissii</i> (9)	<i>V. alginolyticus</i> (69)	<i>V. parahaemolyticus</i> (144)	<i>V. vulnificus</i> (130)	<i>V. carchariae</i> (2)

^aStudied at the CDC *Vibrio* Laboratory and done on Mueller-Hinton agar (with no added NaCl) at 35–37°C.

^bThe numbers in parentheses give the zone size range for the category “intermediate.” For example, “(12–21)” means that resistant strains have 6– to 11-mm zones, strains of intermediate susceptibility have zones that are 12– to 21-mm, and susceptible strains have zones of 22 mm or larger. These particular break points are the ones established in the early 1970s for each antibiotic, and they have been used in our laboratory for over 15 years for taxonomic studies. They may differ slightly from current break points.

from the environment are quite varied because these organisms have been studied in different laboratories, and each has tended to use their own methods. The methods described in this section are taken from Baumann and Baumann (1981) and have proved useful in the research laboratory setting.

Cellular Morphology

CELL SIZE AND SHAPE When examined during the exponential phase of growth in yeast extract broth (YEB) or other relatively simple media, the cells of most *Vibrio* and *Photobacterium* generally appear to be regular, straight or curved rods (Figs. 8, 9, 14, and 15). Many species give rise to involution forms in early stationary phase, a tendency particularly noticeable in some strains of *Photobacterium*. For this reason, it is important to examine the morphology of marine bacteria in the exponential phase of growth in liquid medium. Many of these involution forms are spherical and have been called "spheroplasts" or "round bodies" (Felter et al., 1969; Levin and Vaughn, 1968). These designations are unfortunate since they imply a regularity in the frequently bizarre shapes observed in old cultures (Felter et al., 1969; Kennedy et al., 1970). In *Desulfovibrio aestuarii* and *Nitrospina gracilis*, the formation of "spheroplasts" and "round bod-

ies" was accompanied by a loss of viability (Levin and Vaughn, 1968; Watson and Waterbury, 1971). Baker and Park (1975) have shown that the formation of these structures in stationary phase cultures of a *Vibrio* species correlates with a decrease in the amount of peptidoglycan and loss of viability. The early stages in the formation of involution forms in marine enterobacteria observed by phase contrast microscopy and electron microscopy (Baumann and Baumann, 1981) resemble the K^+ -depleted, plasmolyzed cells of *Alteromonas haloplanktis*. Since the intracellular K^+ content of this organism is involved in the maintenance of turgor and since energy is required for K^+ accumulation and maintenance in the cell (Thompson and MacLeod, 1973), it is possible that one of the early manifestations of cell death is a loss of the ability to maintain a high intracellular K^+ concentration leading to plasmolysis and resulting in structures which subsequently become "spheroplasts," "round bodies," or other involution forms. Colwell (1973) has stated that the formation of "round bodies" is a characteristic of the genus *Vibrio*, but these involution forms are observed in a wide variety of organisms, including strict aerobes of marine origin (Baumann et al., 1972), species of *Photobacterium*, and the nitrifying bacterium *Nitrospina gracilis* (Baumann and Baumann, 1981).

Fig. 14. Different sizes and shapes of *Vibrio* and *Photobacterium* strains seen in electron micrographs. (Parts 1-3 from Allen and Baumann, 1971. Parts 4 and 5 courtesy of R. D. Allen.)

Fig. 15. Different sizes and shapes of *Vibrio* and *Photobacterium* strains seen in phase contrast micrographs and flagella stains. (Parts 6, 7, 10, and 15 from Baumann et al., 1971a; Parts 8 and 9 courtesy of P. Baumann.)

ACCUMULATION OF POLY- β -HYDROXYBUTYRATE (PHB) Many species of marine eubacteria can accumulate PHB as an intracellular reserve product. In the scheme of Baumann and Baumann (1981) for the differentiation of *Photobacterium* species, this trait was of considerable taxonomic importance. In general, the simplest way to observe the accumulation of PHB is to grow the cells in BM medium which is limited for nitrogen (0.02% ammonium sulfate) and contains excess (0.4%) DL- β -hydroxybutyrate. The culture is examined daily with a phase contrast microscope, for a period of 4 days, for the presence of the bright intracellular granules characteristic of PHB (Fig. 15, parts 10 and 13). These granules can also be stained with Sudan black, as described by Burdon (1946). In some cases difficulties are encountered since the granules may be small and, in addition, some marine bacteria, especially in old cultures, have involution forms containing inclusions which may be confused with PHB. In a research setting, PHB can also be identified chemically by alkaline hypochlorite digestion of the cells followed by the solubilization of the PHB in chloroform and precipitation with acetone (Williamson and Wilkinson, 1958). A quantitative estimation of the extracted PHB can be made by spectrophotometric methods.

FLAGELLA STAINS Some strains have tubular projections (Fig. 14), part which are evaginations of the outer membrane of the cell wall (Allen and Baumann, 1971; Baumann et al., 1972) and these might be mistaken for flagella. However, these evaginations are usually readily distin-

guishable from flagella since they are straight and lack the wave form characteristic of flagella. The flagellins of the polar and peritrichous flagella in the same strain differ in their amino acid composition as well as in their immunological properties (Shinoda et al., 1974a, 1974b, 1976). Genetic studies have shown that the peritrichous flagella are essential for swarming on solid media while the polar flagella are necessary for motility in liquid media (Shinoda and Okamoto, 1977).

Carbon Sources Used For Growth

Baumann and Baumann (1981) indicate that the *Vibrio* and *Photobacterium* ferment only a few carbohydrates. Thus, the fermentation tests that have been extremely useful in the identification of Enterobacteriaceae have been of more limited value for the vibrios. Baumann and Baumann (1981) studied many different carbon compounds and found considerable variation among the species in their utilization pattern. Different species of *Vibrio* and *Photobacterium* vibrios use a range of from 14 to 67 organic compounds as sole sources of carbon and energy; these include pentoses, hexoses, disaccharides, sugar acids, sugar alcohols, 2-carbon to 10-carbon monocarboxylic fatty acids, tricarboxylic acid cycle intermediates, and amino acids. Species utilizing aromatic compounds degrade the intermediate protocatechuate by means of a "meta" cleavage. None of the species utilize cellulose, formate, dicarboxylic acids with 6 to 10 carbon atoms, L-isoleucine, L-valine, L-lysine, L-tryptophan, purines, pyrimidines, or *n*-hexadecane.

Extracellular Enzymes

The production of extracellular chitinase, alginase, amylase, gelatinase, and lipase is determined on the appropriate solid medium inoculated as a spot or streak. A positive reaction is observed as a zone of hydrolysis beyond the limits of growth. Several strains can be tested on one plate, or they can be tested in tubes. Chitinase production is tested on yeast extract agar (YEA) plates overlaid with 10–15 ml of modified YEA containing about 5 g colloidal chitin per liter (prepared as described by Berger and Reynolds, 1958) and 2.5 g yeast extract per liter. To test for alginase activity, colloidal chitin is replaced by 20 g of sodium alginate per liter. An overlay method is not needed to detect the presence of amylase, gelatinase, and lipase. To test for these extracellular enzymes, YEA is supplemented with 2 g starch, 50 g gelatin, or 10 ml polyethylene sorbitan monooleate (Tween-80) per liter, respectively. The hydrolysis of chitin or alginate results in a zone of clearing, whereas lipase activity on Tween-80 plates is detected by the appearance of a precipitate of calcium oleate; all three are observed for a period of 7 days. After 48 h of incubation, the starch plates are flooded with Lugol's iodine solution (Stanier et al., 1966) and the gelatin plates with acidic mercuric chloride in order to visualize the unhydrolyzed polymer.

Vibrio Species of Medical Importance

The following sections give a summary of the information available on each of the 12 species of *Vibrios* that are causes of human disease.

Vibrio cholerae

V. cholerae is by far the most important species in the genus *Vibrio*. It has caused many epidemics of cholera and millions of deaths. Once, it was one of the most feared bacterial pathogens in the world (Pollitzer, 1959).

In the mid-1930s, it was recognized that the vast majority of vibrios isolated from cholera cases agglutinated in a single antiserum (Pollitzer, 1959). Agglutination in this antiserum (later called *V. cholerae* O1 antiserum) became the main criterion for identifying a culture as *V. cholerae*. Organisms that did not agglutinate in this serum were given vernacular names such as “nonagglutinating vibrios,” “NAGs,” or “non-cholera vibrios.” These included some organisms known today as *Vibrio cholerae* non-O1, *V. parahaemolyticus*, other *Vibrio* species, and even species of *Aeromonas* or *Plesiomonas*. It was soon

recognized that some of the “NAGs” were identical with *V. cholerae* except for their agglutination in O1 antiserum (Sakazaki and Balows, 1981). However, it has only been in the last few years that these have been classified in the species *V. cholerae*. Today it is accepted that there are two main groups of *V. cholerae* strains—serogroups “O1” and “non-O1.” It is usually convenient to discuss these separately. *V. cholerae* O1 is usually isolated from cholera cases, where it often produces severe watery diarrhea through the action of cholera toxin. *V. cholerae* non-O1 can cause a cholera-like illness but it can also cause a much wider spectrum of disease (Morris et al., 1981), including extraintestinal infections (Hughes et al., 1978).

Vibrio cholerae Serogroup O1

As discussed above this group of *V. cholerae* strains agglutinate in O1 serum, and include serological subtypes Ogawa and Inaba (and Hikojima) (Donovan and Furniss, 1982), and include two biogroups, classical and eltor.

HISTORY The cholera bacillus was isolated by Koch in 1884, so bacteriological confirmation of cholera was possible only after this date. Cholera, or Asiatic cholera as it was often called in early writings, has probably existed in India since ancient times. It may have been found outside of India before 1800, but not in large epidemics. The spread of Asiatic cholera has come in seven large pandemics. The first pandemic began in 1816–1817; six other pandemics followed beginning respectively in 1829, 1852, 1863, 1881, 1889, and 1961 (Pollitzer, 1959), all except the last caused by the classical biogroup. Although the seventh pandemic of 1961 was caused by the eltor biogroup, the classical biogroup has displaced the eltor biogroup in some parts of the Indian subcontinent.

HABITATS *V. cholerae* O1 is found in the human intestinal tract where it can cause a wide spectrum of disease ranging from mild diarrhea to a fatal cholera. The organism is rarely found in other environments unless they have been contaminated with feces from infected individuals. Recent indigenous cases of toxigenic *V. cholerae* O1 infection in the United States and Australia have suggested the possibility of an environmental reservoir.

SYMPTOMS In an area where cholera is endemic, many individuals who ingest *V. cholerae* may have either a mild diarrhea or no symptoms at all (asymptomatic colonization of the intestine with recovery of the organism from formed

stool). This pattern of mild disease was much more common in the seventh (1961) cholera pandemic caused by the eltor biogroup of *V. cholerae*. At the other extreme, some individuals develop an acute diarrhea with constant purging that has been called "cholera gravis." In severe cholera there is massive diarrhea, with large volumes of rice-water stool (clear fluid with flecks of mucus) passed painlessly. The amount of fluid passed can be a liter or more per hour. In 4–6 days this would amount to over twice the body weight. There is usually vomiting and little desire to eat. If untreated, there will be prostration with symptoms of severe dehydration, electrolyte imbalance, painful muscle cramps, watery eyes, loss of skin elasticity and anuria (absence of urine excretion). Death can occur very quickly after onset of symptoms because of the severe dehydration.

TREATMENT Treatment for the most severe cases of cholera is intravenous therapy with large volumes of a simple balanced salts solution which restores water and electrolyte balance and prevents acidosis. Cases with mild or moderate illness are often treated with oral electrolyte solutions. Tetracycline therapy reduces the period of excretion but is not a substitute for rehydration.

Milder forms of diarrhea due to *V. cholerae* O1 are more difficult to distinguish from other mild diarrheas. They can last from 1–5 days with the passage of several liquid stools per day. Cramping and vomiting can also occur. The role of *V. cholerae* O1 can only be shown by isolating and identifying the causative organism. In patients with the eltor biogroup of *V. cholerae* O1, this milder disease is seven times more common than severe cholera.

PATHOGENESIS The pathogenesis of diarrhea due to *V. cholerae* O1 is well understood. The organism is ingested and some cells survive the acid pH of the stomach and pass into the small intestine. The organism colonizes the small intestine and begins to grow and produce cholera toxin. Cholera toxin, which has a molecular weight of 84,000, is composed of an A subunit (molecular weight 21,000), A2 subunit (molecular weight 7,000), and five B subunits (molecular weight 10,000 each). The B subunit of intact cholera toxin attaches to a specific receptor, ganglioside G1, on the cell membrane of cells in the intestine. The A1 subunit of cholera toxin then activates the enzyme adenylate cyclase of the host which then increases the level of cyclic AMP, leading to the hypersecretion of salt and water. The net result is the massive outpouring of liquid stool and resulting dehydration which is typical of cholera.

SOURCES *V. cholerae* O1 is an intestinal pathogen, and the vast majority of strains come from human feces (Tables 2 and 3). Only a few human isolates are extraintestinal. *V. cholerae* O1 can also be isolated from the environment and from other animals that come in contact with feces of cholera cases. There are occasionally reports of *V. cholerae* O1 from environmental sources that are unlikely to have come from cholera cases. Most of these strains do not produce cholera toxin, and may represent strains of *V. cholerae* from an evolutionary line unrelated to the one that causes pandemic cholera. They are more similar to the *V. cholerae* non-O1 strains in their clinical and public health importance.

GEOGRAPHICAL DISTRIBUTION The World Health Organization (WHO) regularly reports the world-wide distribution of reported cholera cases. In its survey for 1989, 48,403 cases were reported from 35 countries, but some governments probably do not report cases for political and economic reasons. Almost all of the cases were in Africa (35,606) and Asia (12,785).

The history of cholera (defined to be the disease caused by toxin-producing *V. cholerae* O1) in the United States is quite interesting (Blake et al., 1980a). The last case of cholera in the United States from a pandemic occurred before 1900. Then, unexpectedly, there was an isolated case from Texas in 1973. This was followed by an outbreak in Louisiana in 1978, two sporadic cases in Texas in 1982, and an outbreak on an oil-drilling platform on a bayou near the Texas coast in 1982, with sporadic cases since. These strains have been thoroughly studied and have the following properties in common: serogroup Inaba (see Table 10), cholera toxin positive, strongly hemolytic, and a unique bacteriophage lysis pattern. When compared to other strains from the seventh pandemic of cholera, the American strains are quite different, suggesting that this is a different clone. Apparently, a similar situation is occurring in Australia, which has its own unique clone(s).

ISOLATION In rice-water stools from cholera cases, *V. cholerae* is usually present essentially as a pure culture and in very high numbers (10^6 to 10^8 organisms per ml stool). Isolation will present no problem in these cases (Figs. 6, 7, 8, and 11). In formed feces, the organism will probably be present in much lower numbers and normal enteric flora will also be present. Enrichment in alkaline peptone water and plating on a highly selective medium will yield some additional positive cultures in this situation (Balows et al., 1971).

IDENTIFICATION In countries where cholera is common there is no need to do a large number

of biochemical tests to confirm a culture as *V. cholerae*. However, complete biochemical testing should be done in countries where cholera is rare (Tables 6 to 11). The test for the Na⁺ requirement differentiates *V. cholerae* from the halophilic *Vibrio* species (Table 6). Sucrose fermentation differentiates *V. cholerae* from *V. mimicus* (Table 8). The decarboxylase pattern of arginine negative, lysine positive, and ornithine positive differentiates (with one exception) *V. cholerae* from the oxidase-positive fermentative species in *Aeromonas* and *Plesiomonas*.

ANTIBIOTIC SUSCEPTIBILITY Resistance is rare in *V. cholerae*. Most strains are susceptible to tetracycline, the drug of choice. Occasionally a strain of *V. cholerae* becomes resistant and can spread. This usually happens in cholera-endemic areas where there is more chance for a strain to acquire an antibiotic resistance plasmid. Susceptibility to the polymyxin group of antibiotics is a property used to differentiate the classical and eltor biogroups (Table 9).

Vibrio cholerae Non-O1

This group of organisms is strikingly similar to *V. cholerae*, but they do not agglutinate in O1 antiserum. They can cause a cholera-like disease, but are usually isolated from patients with mild diarrhea and from extraintestinal infection and the environment, which is a very important reservoir. These organisms were originally not classified in the species *V. cholerae* but were reported as "nonagglutinating vibrios," "NAGs," or "non-cholera vibrios." Now, however, they are classified as *V. cholerae* non-O1, much data are appearing on their ecology (Colwell, 1984) and role in human disease (Hughes et al., 1978; Morris et al., 1981).

HABITATS Strains of *V. cholerae* non-O1 have been isolated from patients with severe dehydrating (cholera-like) gastroenteritis. Other strains have been isolated from patients with mild diarrhea. Unlike *V. cholerae* O1, the non-O1 strains have also been found in patients with diarrhea and fever whose feces have contained blood and/or mucus.

Although the pathogenic process is not as well known as is that of *V. cholerae* O1, three possible mechanisms have been postulated: 1) production of cholera (or cholera-like?) toxin; 2) production of a heat-stable enterotoxin (positive in the infant mouse assay used for *Escherichia coli* heat-stable enterotoxin); or 3) invasive disease (positive response to whole cells but not to cell filtrates in the ligated rabbit ileal loop or infant mouse assay). However, some strains of *V. cholerae* non-O1 have no positive response in any of

the above assays, so the correlation of the possible virulence factors and the different types of gastroenteritis-invasive diarrhea need further investigation.

EXTRAIESTINAL INFECTIONS *V. cholerae* non-O1 has a wider spectrum of disease than the *V. cholerae* O1. Non-O1 strains have been isolated from patients with septicemia who have cirrhosis and/or other underlying disease. In our collection (Table 3), there were 42 blood isolates, compared with only one blood isolate of *V. cholerae* O1. The non-O1 strains were also isolated from ears, wounds, respiratory tract, and urine. There were 52 isolates from these sources compared with only two for *V. cholerae* O1 (Table 3).

GEOGRAPHICAL DISTRIBUTION *V. cholerae* non-O1 strains have been isolated worldwide both from patients and the environment. In the United States many are found in sporadic cases of diarrhea. Most of these have occurred after eating raw oysters. In the United States less than 5% of the isolates have been positive for cholera toxin; this is in contrast to the situation in Bangladesh where about one-third of the isolates have been positive (Blake, 1981).

ISOLATION AND IDENTIFICATION The discussion for *V. cholerae* O1 also applies to the non-O1 strain. The essential difference is that the O1 strains agglutinate in antiserum to *V. cholerae* O1 but the non-O1 strains do not. The biochemical reactions of both *V. cholerae* groups are almost identical.

SEROTYPING Strains of *V. cholerae* non-O1 can be further differentiated by serotyping by one of several systems (Brenner et al., 1982; Smith, 1979). In a system described by Sakazaki and Shimada (1977), antisera are made against heated cells, and the O antigen is determined by agglutination. There are over 60 different O antigens in this schema. In a system described by Smith (Smith, 1979), antisera are made against unheated cells, and the "Smith type" is determined by slide agglutination of living cultures. There are over 72 different types in the Smith schema. Serological typing of non-O1 *V. cholerae* should be done only to answer specific epidemiological questions, and is done by only a few reference laboratories. An international working group has been proposed to study the two systems and make recommendations for standardization.

Vibrio mimicus

Vibrio mimicus is a species of *Vibrio* (Davis et al., 1981) that apparently causes diarrhea, usu-

ally after the consumption of uncooked seafood, particularly raw oysters (Shandera et al., 1983). *V. mimicus* has been isolated from many countries (Canada, Mexico, Philippines, New Zealand, Guam, Bangladesh) which suggests a worldwide distribution in countries situated along an ocean. The isolation of *V. mimicus* from water, oysters, and shrimp, and its distribution in coastal areas indicate that its ecology may be similar to the ecology of *V. cholerae* non-O1.

HISTORY There have been a number of reports of *V. cholerae* strains with atypical biochemical reactions. Traditionally they have been reported with designations such as “*V. cholerae*—lysine-decarboxylase negative,” “*V. cholerae*—mannitol negative,” or “*V. cholerae*—sucrose negative.” Davis et al. (1981) studied representative strains from six of these unusual biogroups by both DNA hybridization and phenotypic analysis. Five of the six groups were highly related to *V. cholerae* by DNA hybridization. These had been identified correctly as “atypical strains of *V. cholerae*.” However, the group of sucrose-negative strains was only 24–54% related to *V. cholerae*. Based on this low relatedness and on their phenotypic differences, Davis et al. (1981) proposed a new species, *Vibrio mimicus*. The name “mimicus” refers to the fact that the strains “mimic” *V. cholerae*.

HABITATS *V. mimicus* has been isolated from diarrhea cases, extraintestinal infections, and the environment. Based on the information submitted with cultures, Davis et al. (1981) suggested that *V. mimicus* may be a new cause of diarrhea, probably linked to eating shellfish. Three strains of *V. mimicus* were positive for heat-stable enterotoxin in the infant mouse assay and five were positive for heat-labile enterotoxin in the Y-1 adrenal cell assay or in the ELISA assay. However, other strains from diarrhea cases were negative in the assays. The enterotoxin data were very similar to those for *V. cholerae* non-O1 strains in that some produced heat-labile or heat-stable enterotoxin, but most strains from patients with diarrhea produce neither toxin.

ISOLATION AND IDENTIFICATION Most of the *V. mimicus* strains have been isolated during a search for *V. cholerae* and other *Vibrio* species. *V. mimicus* grows well on TCBS agar and forms green (sucrose-negative) colonies (Table 4). *V. mimicus* grows well on the usual enteric media and in nutrient broth with no added NaCl. Isolation and identification should pose no special problems.

BIOCHEMICAL REACTIONS Tables 6 to 8 give the reactions of *V. mimicus* and compare them with

those of *V. cholerae*. These two species are very similar in most of the tests normally needed for identification; however, Table 8 gives reactions which are useful for differentiation. *V. mimicus* is negative for lipase production and sucrose fermentation. *V. cholerae* usually has the opposite pattern, although a few strains are lipase negative. *V. mimicus* resembles the “classical biogroup” of *V. cholerae* because it is Voges-Proskauer negative and susceptible to polymyxin. The “eltor biogroup” of *V. cholerae* is usually Voges-Proskauer positive and resistant to polymyxin. *V. mimicus* grows in nutrient broth without added NaCl, a reaction which differentiates it, along with *V. cholerae*, from the halophilic *Vibrio* species that require higher NaCl concentration for growth.

Vibrio parahaemolyticus

V. parahaemolyticus has been known as a cause of acute gastroenteritis since 1950 (Zen-Yoji et al., 1965). Foodborne outbreaks and sporadic cases occur worldwide and are usually associated with the consumption of contaminated seafood. Two books (Fujino et al., 1974; Miwatani and Takeda, 1976) and a review (Joseph et al., 1982) summarize much of the information known about this organism.

HISTORY On 20 and 21 October 1950, there was an outbreak of food poisoning in Osaka, Japan, involving 272 patients with acute gastroenteritis and 20 deaths. This led to an extensive investigation and eventually an organism was isolated which was shown to be the etiological agent. The fascinating account of this discovery can be found in Miwatani and Takeda (1976, p. 1–5). The organism was studied and named as a new species, *Pasteurella parahaemolytica*. Its halophilic nature was not discovered until 1955 (Miwatani and Takeda, 1976), when it was reclassified as a halophilic *Vibrio* species, *V. parahaemolyticus*.

SYMPTOMS *V. parahaemolyticus* causes gastroenteritis with nausea, vomiting, abdominal cramps, low-grade fever, and chills (Barker and Gangarosa, 1974). The diarrhea is usually watery but can sometimes be bloody. The disease is usually mild and self-limiting but can be fatal (a 7% fatality rate was reported in the first outbreak). There is a good correlation between pathogenicity and a positive Kanagawa test (a test which measures the ability of the strain to produce a hemolysin for human red blood cells when grown on a special medium; Ljungh and Wadstrom, 1983). About 96% of the *V. parahaemolyticus* strains from well-documented cases of human gastroenteritis are Kanagawa positive,

but only about 1% of the strains isolated from the environment are positive. Although there is excellent correlation between this hemolysin and human disease, the mechanisms of pathogenesis are still unclear, since other toxins or virulence factors may be involved. Rehydration is usually the only treatment needed, but in some severe cases the patient will require hospital admission. Antimicrobial therapy may be beneficial, and tetracycline appears to be the drug of choice.

Outbreaks of gastroenteritis due to *V. parahaemolyticus* occur worldwide, but are not common in the United States. In Japan, *V. parahaemolyticus* is an extremely important diarrheal agent, and causes 50–70% of the cases of food-borne enteritis (Sakazaki and Balows, 1981). All of the outbreaks were associated with seafood either directly or indirectly. Direct infection comes from the ingestion of raw fish or shellfish which are contaminated with the organism. This mechanism of transmission is apparently quite common in Japan because of the national custom of eating raw fish (Sakazaki and Balows, 1981). Contamination after cooking apparently is the mechanism of indirect infections.

ISOLATION Much has been written about the isolation of *V. parahaemolyticus*. The fact that it was not detected as an important cause of gastroenteritis until 1950 indicates that isolation with the usual enteric media can pose problems. Oxidase testing of colonies on a nonselective medium such as blood agar should provide a high isolation rate. A plate of TCBS medium (Table 4) can be included in those geographical areas where *V. parahaemolyticus* is most common. The isolation methods designed for *V. cholerae* are also efficient for *V. parahaemolyticus*. *V. parahaemolyticus* grows well on TCBS agar as green colonies 2 to 3 mm in diameter.

IDENTIFICATION *V. parahaemolyticus* is one of the halophilic *Vibrio* species (Baumann and Baumann, 1973; Twedt et al., 1969) belonging in the lysine-positive, arginine-negative group (Table 6). It is negative for the Voges-Proskauer test and for fermentation of lactose and salicin. These and other tests are useful in differentiation (see Tables 6, 7, and 14).

UREA-POSITIVE STRAINS Initially, all strains of *V. parahaemolyticus* were reported to be negative for urea hydrolysis. Sakazaki and Balows reported that none of their 2,354 strains were urea positive (Sakazaki and Balows, 1981). However, in the last decade we have received many strains which were otherwise typical of *V. parahaemolyticus* but were urea-positive. These urea-positive strains were confirmed by DNA hybridization as *V. parahaemolyticus* (Brenner et

al., 1983a). In our laboratory the number of urea-positive strains has increased significantly: 1977, 17% urea-positive; 1978, 14% positive; 1979, 36% positive; 1980, 12% positive; 1981, 47% positive; 1982, 73% positive; and 1983, 83% positive, etc. This sample is biased because laboratories refer atypical strains rather than typical ones. However, in recent years, 50% or more of *V. parahaemolyticus* strains from California and from outbreaks investigated by CDC have also been urea-positive. These samples are less biased, and show that the increase in urea-positive strains is real.

SEROTYPING A serological typing schema for *V. parahaemolyticus* includes 11 numbered O antigens and 55 numbered K antigens. The O antigen is first determined by slide agglutination with an autoclaved antigen. The K antigen is then determined by slide agglutination with an unheated suspension. A complete set of O and K antisera (individuals and pools) is produced commercially by Toshiba Kagaku Kogyo Co., Inc., Maruishi Bldg. 2, 1-Chrome Kanda-Kajicho, Chiyode-KU, Tokyo, Japan. It may still be available in the United States from Nichimen Company, Inc., 1185 Avenue of the Americas, New York, NY 10036. Serotyping of *V. parahaemolyticus* should be done in reference laboratories and only to answer specific epidemiological questions.

ANTIBIOTIC SUSCEPTIBILITY *V. parahaemolyticus* is usually resistant to ampicillin and carbenicillin, but susceptible to colistin (Table 17). These properties are shared with *V. alginolyticus*, but *V. vulnificus* has the opposite susceptibilities (Bonner et al., 1983) (Table 15).

Vibrio hollisae

V. hollisae is a halophilic species (Hickman et al., 1982) that is associated with diarrhea following consumption of raw seafood.

HISTORY *V. hollisae* was named as a new species in 1982 (Hickman et al., 1982). Two laboratories had independently studied this organism under the vernacular names "EF13" and "Enteric Group 42." DNA hybridization studies indicated that these strains were highly related and distinct from other named *Vibrio* species, so Hickman et al. (1982) named this organism *Vibrio hollisae*.

HABITATS *V. hollisae* probably causes human diarrhea. Its association with diarrhea is very strong, but additional evidence is needed to further document its causal role and pathogenesis. Fifteen of the original sixteen strains were from feces, and many of the patients had diarrhea

(Hickman et al., 1982). Morris et al. (1982) described the clinical and epidemiological features of 11 diarrhea cases that were culture positive for *V. hollisae*. They also reported one isolate from blood. It was from a patient with hepatic cirrhosis, hepatic encephalopathy, bronchopneumonia, and sepsis due to the yeast *Cryptococcus*. The patient was comatose and died two days after hospital admission.

ISOLATION Laboratory strains of *V. hollisae* do not grow on TCBS agar (Table 4) or MacConkey agar (2 days, 36°C). Since these two media are frequently used for the isolation of *Vibrio* and Enterobacteriaceae from stools, it is possible that *V. hollisae* is often missed, even though it may be the predominant organism. *V. hollisae* grew well on sheep blood agar (36°C), so it can be detected by the use of the oxidase reagent as previously discussed.

IDENTIFICATION *V. hollisae* does not grow in nutrient broth without added NaCl, thus it is one of the halophilic *Vibrio* species. Tables 6 and 7 give its biochemical reactions, and only a few reactions need comment. *V. hollisae* is indole positive when tested in heart infusion broth with 1% NaCl added (Table 1), but only 38% positive in peptone water with 0.5% NaCl (the usual content). Moeller's lysine, arginine, and ornithine are all negative, which is a distinguishing characteristic (Table 6). Motility in *V. hollisae* is very slow. None of the strains were motile in semisolid medium after 48 h incubation at 36°C, but 88% were motile after 7 days. This is an unusual characteristic for the genus *Vibrio*. *V. hollisae* ferments only D-glucose, L-arabinose, D-galactose and D-mannose; this is a characteristic fermentation pattern among *Vibrio* species. Recently we confirmed a urea-positive strain of *V. hollisae*, the first one we have seen with this unusual property.

ANTIBIOTIC SUSCEPTIBILITY Strains of *V. hollisae* have a very characteristic antibiogram. There are very large zones around all antibiotics tested, including penicillin (Table 17).

Vibrio fluvialis

V. fluvialis appears to cause sporadic cases of diarrhea worldwide (Lee et al., 1981; Nishibuchi and Seidler, 1983; Tacket et al., 1982), and it has been implicated in outbreaks of diarrhea in Bangladesh (Huq et al., 1980).

HISTORY Lee et al. (1981) gave the name *Vibrio fluvialis* to a group of halophilic vibrios that had been previously been known as "Group F vibrios" (Lee et al., 1978b) and as "Group EF6."

These organisms had been isolated from a number of environmental sources throughout the world and from humans with diarrhea. Lee et al. (1981) defined two biogroups in this species which correlated with source of isolation and certain biochemical tests. *V. fluvialis* biogroup I did not produce gas during fermentation (it was "aerogenic") and was isolated from human diarrhea as well as the environment. *V. fluvialis* biogroup II produced gas during fermentation (it was "aerogenic") and was isolated from the environment, but not from humans with diarrhea. Brenner et al. (1983b) later used DNA-DNA hybridization to show that strains of *V. fluvialis* biogroup II were related to strains of *V. fluvialis* biogroup I, but they were sufficiently different to be a new species that they named *V. furnissii*.

HABITATS The sources of early clinical isolates of *V. fluvialis* showed a marked association with diarrhea (Lee et al., 1981), and further studies have strengthened its causative role. One difficulty in assessing the clinical symptoms and epidemiology of *V. fluvialis* has been the presence of other possible pathogens. Most of the reports have come from geographical areas where several possible pathogens are often present in feces.

Gastroenteritis caused by *V. fluvialis* is usually described as "cholera-like." Patients typically have watery diarrhea with vomiting (97%), abdominal pain (75%), moderate to severe dehydration (67%), and often fever (35%). Usually infants, children, and young adults are affected. Frank blood is found in a small percentage of stool samples, but red or white blood cells are found in most cases (75%).

The pathogenesis of *V. fluvialis* diarrhea is not completely known. Assays for heat-labile and heat-stable enterotoxin (LT and ST) and invasiveness have generally been negative. About 20% of strains give a positive rabbit ileal loop test for enterotoxin. Recent studies have provided additional evidence for enterotoxin or for "enterotoxin-like" molecules (Lockwood et al., 1982; Nishibuchi and Seidler, 1983).

ISOLATION *V. fluvialis* grows on TCBS agar as 2- to 3-mm yellow colonies (Table 4). Although it requires Na⁺ for growth, the requirement is much lower than some of the more halophilic *Vibrio* species, which makes isolation and identification easier. Nishibuchi et al. (1983) recently described a selective broth for isolating this species from water.

IDENTIFICATION The most striking aspect of *V. fluvialis* identification is the possible confusion with *Aeromonas*, since both species are arginine-dihydrolase positive. Many cultures sent to us

labeled "possible *V. fluvialis*" turn out to be *Aeromonas*. The converse is also true. A simple test to differentiate these two organisms is growth in nutrient broth with 0% and 1% NaCl. *V. fluvialis* is a halophilic vibrio and will not grow without the added NaCl whereas strains of *Aeromonas* grow in both media (Table 12). *V. fluvialis* is generally susceptible to antibiotics (Table 17).

Vibrio furnissii

This species was formerly known as "*V. fluvialis* biovar II," "*V. fluvialis* aerogenic," or "*V. fluvialis* gas⁺." It is now recognized as a separate species, *V. furnissii* (Brenner et al., 1983b).

HABITATS This species has been isolated from human clinical specimens and the environment. The vast majority of the original isolates of *V. fluvialis* (which included *V. furnissii* from patients with diarrhea) did not produce gas during fermentation. Thus, they are *V. fluvialis*.

Further investigation indicated that *V. furnissii* had been isolated from two outbreaks of acute gastroenteritis among American tourists returning from the Orient in 1969. Other pathogens or possible pathogens were also isolated (*V. parahaemolyticus*, *V. cholerae* non-O1, *V. fluvialis*, *Salmonella*, and *Plesiomonas*), so the causal role of *V. furnissii* was very doubtful. There have been no documented cases of diarrhea caused by this organism. Thus we have not included it with the other *Vibrio* species as a probable cause of diarrhea. However, microbiologists should be alert to its presence and for evidence which might show that it has a causal role in diarrhea. *V. furnissii* is apparently rare in human clinical specimens. Table 3 indicates that human stool was the most common source (16 isolates), but one isolate was from a wound. Lee et al. (1981) mentions that *V. furnissii* (listed as *V. fluvialis* biovar II) is widespread in the aquatic environment and is more common in estuaries.

ISOLATION AND IDENTIFICATION Table 7 indicates that *V. furnissii* resembles *V. fluvialis* very closely. The two species are so close phenotypically that only a few tests are useful in differentiating them (Tables 12 and 13). Gas production will be the key differential test in most clinical laboratories (Table 13). *V. furnissii* can also be confused with *Aeromonas* if its halophilic nature is not recognized.

Vibrio vulnificus

V. vulnificus has been recognized as a distinct species of *Vibrio* since 1976 (Baumann and Schubert, 1984). It causes wound infections and life-threatening septicemia (Blake et al., 1979). In

the last few years, there has been intensive study of this organism (Baumann and Schubert, 1984; Blake, 1981; Colwell, 1984; Sakazaki and Balows, 1981; Tison and Kelly, 1984).

HISTORY Hollis et al. (1976) described a salt-requiring organism that appeared to be different from other *Vibrio* species. It was similar to *V. parahaemolyticus* and *V. alginolyticus* in many of its biochemical reactions, but the new organism fermented lactose. The vernacular name "lactose-positive *Vibrio*" was given to this organism, and in the literature it has been referred to as "*L⁺ Vibrio*" and "*Lac⁺ Vibrio*." The organism was studied in several laboratories (Clark and Steigerwalt, 1977), and given the scientific name *Beneckea vulnifica* by Reichelt et al. (1976). Classification of the organism in the genus *Beneckea* was not widely accepted, so it was subsequently classified in the genus *Vibrio* (Farmer, 1979). Today, it is almost universally known as *V. vulnificus*.

HABITATS *V. vulnificus* is widely distributed in the marine environment, where some strains come in contact with humans and cause infections. This species has been associated primarily with two disease syndromes, primary septicemia and wound infection (Blake et al., 1979). Primary septicemia is a very serious infection with a fatality rate of about 50%. Most patients with primary septicemia due to *V. vulnificus* have pre-existing liver disease (Blake et al., 1979); but some were healthy individuals (Tison and Kelly, 1984). In most cases the disease begins several days after the patient has eaten raw oysters. Cultures of blood and skin lesions are usually positive for *V. vulnificus*. *V. vulnificus* also causes severe wound infections, usually after trauma and exposure to marine animals or the marine environment (Blake et al., 1979). The mortality rate is not nearly as high as in primary septicemia cases (about 7% compared to about 50%). Other infections from which *V. vulnificus* has been isolated include pneumonia in a drowning victim and endometritis which developed in a woman after exposure to seawater (Tison and Kelly, 1984).

PATHOGENESIS Animal studies have shown that *V. vulnificus* can cause severe local infections with gross edema leading to tissue necrosis and death. Iron availability appears to be important in pathogenesis (Tison and Kelly, 1984). A toxin produced by *V. vulnificus* has been demonstrated, although its role is still unclear.

SOURCES Table 3 gives the sources of our isolates. The vast majority were from blood or wound. Unusual sources included one from

urine and five from stool. *V. vulnificus* is also frequently isolated from the marine environment which is not apparent from our collection that is weighted toward human clinical specimens.

ISOLATION *V. vulnificus* grows well on blood agar and TCBS agar. Although most strains of *V. vulnificus* are sucrose-negative (only 3% were positive in the original report of Hollis et al., 1976), the number of sucrose-positive strains in our collection has increased markedly over the years. Thus, on TCBS agar, *V. vulnificus* can be either green (most) or yellow (some) (Table 4). This fact has not always been considered in studies looking for it in the environment. Most isolations of *V. vulnificus* in clinical laboratories will be made on blood agar, since blood and wounds are the usual sources. Commercial blood culture bottles usually support growth of *V. vulnificus*, however the Na⁺ content is probably suboptimal, which may yield some cells with aberrant sizes and shapes. *V. vulnificus* does not survive well on media with an NaCl content of only 0.5% NaCl. Often cultures that have been shipped to us on ordinary enteric media are nonviable.

IDENTIFICATION *V. vulnificus* is a halophilic *Vibrio* species. It is lysine positive, and arginine negative, and is in the same group as *V. parahaemolyticus* and *V. alginolyticus* (Tables 6, 7, and 14). It is differentiated by lactose fermentation, the ONPG test, salicin and cellobiose fermentation and several other tests (Table 4). The antibiogram (disk diffusion) is also helpful in differentiating these three species (Table 14). *V. vulnificus* has either no zone or a small zone around the colistin disk, but large zones around ampicillin and carbenicillin. *V. parahaemolyticus* and *V. alginolyticus* have the opposite pattern. Although *V. vulnificus* is susceptible to most antibiotics used against Gram-negative bacteria, animal studies indicate that tetracycline may be most effective in vivo (Tison and Kelly, 1984).

Vibrio damsela

V. damsela is a *Vibrio* species that appears to cause human wound infections. It is found in the marine environment and causes skin lesions on certain marine fish.

HISTORY *V. damsela* was described by Love et al. (1981). The original isolates were from skin lesions on damselfish on the California coast. Koch's postulates were fulfilled when it was documented that this organism alone caused the fish lesions. Strains of *V. damsela* were then compared to our collection of unidentified *Vibrio* strains from human clinical specimens, which revealed that *V. damsela* had occurred in human

infections (Love et al., 1981). The strains from marine fish, human clinical specimens, and the environment were studied, and *V. damsela* was proposed as a new species.

HABITATS *V. damsela* has been isolated from the marine environment, marine fish, and human clinical specimens. Morris et al. (1982) reviewed the case histories of six patients with wound infections whose isolates had been sent to our laboratories from 1971 to 1981. All had been acquired in coastal areas. *V. damsela* appears to cause human wound infections, but its causal role needs to be further documented. The sources of our *V. damsela* isolates are given in Table 3. All of the clinical isolates were from wounds, and 9 of the 10 were leg or foot wounds. Strains were also from marine animals, particularly marine fish. A number of fish from Dakar, Senegal, also yielded this organism. Others were from sewage, oysters, and a wound on a raccoon.

ISOLATION *V. damsela* grows on blood agar and other noninhibitory media, but the Na⁺ content is less than optimum. Strains grow on TCBS agar as 2–3 mm green or yellow colonies (Table 4). Love et al. (1981) noted that the damselfish isolate grew much better on TCBS at 25°C than 36°C. There have been few details on the isolation of this organism from human clinical specimens.

IDENTIFICATION The complete biochemical reactions of *V. damsela* are given in Table 7. It is a typical halophilic *Vibrio* in many respects. Strains do not grow in nutrient broth without added NaCl, which indicates its requirement for Na⁺. *V. damsela* is arginine positive, Voges-Proskauer positive and has a characteristic fermentation pattern, positive for D-glucose, D-mannose, and usually for D-galactose and trehalose. The characteristics which differentiate it from other *Vibrio* species are given in Tables 6, 7, and 12.

ANTIBIOTIC SUSCEPTIBILITY *V. damsela* is generally susceptible to antibiotics, but less so than many other *Vibrio* species (Table 16).

Vibrio alginolyticus

V. alginolyticus is very common in the marine environment (Stephen et al., 1978) and also occurs in human clinical specimens.

HISTORY *Vibrio parahaemolyticus* was the first of the halophilic *Vibrio* species to be studied in detail. An organism similar to, but different from, *V. parahaemolyticus* was often isolated from the marine environment, but not from patients with gastroenteritis. This organism was

originally called "biotype 2 of *V. parahaemolyticus*" (Sakazaki, 1968). However, a number of studies have shown it to be a distinct species, now universally known as *V. alginolyticus* (Sakazaki and Balows, 1981; Sakazaki et al., 1963).

HABITAT Many papers describe the isolation of *V. alginolyticus* from soft tissue infections (Pien et al., 1977; Rubin and Tilton, 1975). Wound infections and ear infections are usually mentioned, with eye infections mentioned much less frequently. The data show the definite association of *V. alginolyticus* with infection at these sites, however the etiological role and pathogenesis of this organism have not been thoroughly shown. However, most authors list *V. alginolyticus* as a pathogenic *Vibrio* species, particularly of wound and ear infections. Antibiotic treatment has been used in most cases and surgical debridement has been used in some.

Table 3 gives the sources of the 74 isolates of *V. alginolyticus* in our collection. Wounds and ears are the most common sources. Interestingly, there were 12 isolates from foot or leg wounds, but only one from hand or arm wounds. *V. alginolyticus* is also widely distributed in the marine environment (Furniss et al., 1978; Sakazaki and Balows, 1981). Most clinical isolates probably come from patients exposed to the marine environment, particularly after trauma.

Isolation and Identification

V. alginolyticus is a marine *Vibrio* and requires added NaCl for optimum growth. However, it grows well on many of the enteric media. It is sucrose-positive and occurs as 2–3 mm yellow colonies on TCBS agar (Table 4). It is easy to isolate from saltwater samples. A small volume is spread on a marine agar plate, which is then incubated at 25°C. After 18–24 of incubation, the plate is observed for colonies that swarm in a way similar to *Proteus*. A colony is restreaked onto marine agar and to TCBS agar (to prevent swarming) for purity and then identified. Many of the swarming colonies will be *V. alginolyticus* (de Boer et al., 1975a, 1975b).

Table 7 lists the properties of this species. It is lysine-positive and arginine-negative, which puts it into the group with *V. parahaemolyticus* and *V. vulnificus* (Table 6). *V. alginolyticus* is usually Voges-Proskauer positive and grows in nutrient broth with 8 and 10% NaCl, which differentiates it from the other two species (Table 4).

ANTIBIOTIC SUSCEPTIBILITY *V. alginolyticus* is usually resistant to ampicillin and carbenicillin but susceptible to colistin (Table 17). This pattern is similar to *V. parahaemolyticus*, but *V. vulnificus* has the opposite reactions (Table 14).

Vibrio metschnikovii

V. metschnikovii is a species in the genus *Vibrio* that has been frequently isolated from fresh, brackish, and marine waters, but rarely from human clinical specimens (Lee et al., 1978a).

HISTORY In 1884, Gamalria reported the isolation of a new organism, *Vibrio metschnikovii*, from a fowl that had died of a "cholera-like" disease (Lee et al., 1978a). Little was written about the organism until Lee et al. (1978a) began isolating similar organisms on TCBS agar from marine and freshwater environments in the United Kingdom. These strains were oxidase-negative and did not reduce nitrate to nitrite, but otherwise were quite typical halophilic *Vibrio* species. They proposed that the strains be classified as *V. metschnikovii* and wrote an amended description of this organism (Lee et al., 1978a).

HABITATS Lee et al. (1978a) described 40 strains of *V. metschnikovii* but none were from human clinical specimens; however, Jean-Jacques et al. (1981) reported the first clinically significant isolate of this newly redefined species. An 82-year-old woman with peritonitis and an inflamed gallbladder yielded *V. metschnikovii* from a positive blood culture. The isolate was considered clinically significant.

Table 3 gives the sources of the isolates in our collection. An unusual finding was the two strains from urine. One was from the midstream urine of an 80-year-old woman in Canada. The other was from a routine urine culture of a 65-year-old man with chronic alcoholism, poorly controlled diabetes, and incontinence and urinary frequency. Another interesting isolate was from a wound: A 64-year-old female with peripheral vascular disease and on renal dialysis developed an ulcer around a bunion on her foot, which was treated by a wedge resection, followed by a foot amputation and finally a below-the-knee amputation. The wound yielded *V. metschnikovii* along with five other possible pathogens. The patient went fishing frequently, which may have been her source of *V. metschnikovii*. Further study is needed to determine the clinical significance of *V. metschnikovii* from sources such as urine and wound.

Nonhuman sources include rivers, sewage, cockles, shrimp, lobster, crab, and fowl (Lee et al., 1981; and our own data). These data suggest that *V. metschnikovii* is widely distributed in the environment and that humans may occasionally become colonized or possibly infected from these sources.

ISOLATION AND IDENTIFICATION *V. metschnikovii* grows on TCBS agar as 2–3 mm yellow colonies

(Table 4), and apparently grows well on other laboratory media. It requires Na^+ for growth but in much smaller amounts (5 to 15 mM) than the other Na^+ requiring *Vibrio* species (Baumann and Schubert, 1984). Table 7 gives the characteristics of *V. metschnikovii*. It is very easy to identify because it is oxidase negative, does not reduce nitrate to nitrite, and requires Na^+ for growth (Table 7). These three properties differentiate it from all the other species of Enterobacteriaceae and Vibrionaceae. *V. metschnikovii* is generally susceptible to antibiotics (Table 17).

Vibrio cincinnatiensis

Little is known about this species, which was first reported by Brayton et al. (1986) from a case of bacteremia and meningitis that yielded an unusual isolate of the genus *Vibrio*. Biochemical testing and 5S ribosomal RNA sequencing led to the conclusion that this was a new species, which was named *V. cincinnatiensis*.

ISOLATION AND IDENTIFICATION *V. cincinnatiensis* grows very poorly on TCBS medium (Table 4), but isolates from extraintestinal clinical specimens should grow on one of the normal plating media such as blood agar. *V. cincinnatiensis* requires salt for growth (Table 7), and ferments myo-inositol (Table 6), which should make it easy to identify.

Vibrio carchariae

Grimes et al. (1984) studied two urease-positive halophilic vibrios isolated from a brown shark (*Carcharhinus plumbeus*) that had died in captivity in a large aquarium. One of the organisms (strain 1116a) was identified as *V. damsela*, but the other (strain 1116b) could not be identified. After further phenotypic testing and DNA-DNA hybridization, Grimes et al. (1984) concluded that this was a new species and named it *V. carchariae*. *V. carchariae* has now also been found in human clinical specimens.

HABITATS *V. carchariae* has been isolated from other sharks since the original report, but it has also been shown to occur in human clinical specimens. Pavia et al. (1989) described a case in which the organism was isolated from a wound following a shark bite. An 11-year-old girl was attacked by a shark while wading in knee-deep water off the coast of South Carolina. She sustained several deep lacerations to her left calf that became infected after subsequent surgery. A culture from the infected wound yielded an unusual vibrio that was subsequently identified as *V. carchariae*.

ISOLATION AND IDENTIFICATION *V. carchariae* appears to grow on plating media such as chocolate agar and MacConkey agar (Pavia et al., 1989), and grows well on TCBS agar as yellow colonies (Table 4). It is a halophilic vibrio and is similar to *V. parahaemolyticus*, *V. alginolyticus*, and *V. vulnificus* in its biochemical properties, but can be differentiated (Table 14). Strains are resistant to ampicillin, carbenicillin, and colistin (Table 17).

***Vibrio* Species That Do Not Occur in Human Clinical Specimens**

In addition to the 12 *Vibrio* species discussed above that occur in clinical specimens, there are over 20 marine species that apparently do not. Theoretically, these marine vibrios could occur in feces following ingestion of environmental water or uncooked seafood, and we have some evidence that this occurs. Many of the species have few literature citations (see Table 1 in Chapter 156), and this group has not been studied as thoroughly as the human pathogens. Table 15 gives the phenotypic properties of these species based on the methods used in our laboratory. Some of the biochemical test results at 25°C in media with added marine cations differ from those originally published. This may reflect the different methods used since these types of differences are not unusual in "between-laboratory" comparisons. These marine species are briefly described in the following sections.

Vibrio anguillarum

V. anguillarum is a marine vibrio that causes disease in marine fish and other marine animals (Baumann et al., 1978; Sakazaki and Balows, 1981; Smith, 1961). The most important is a septicemic disease in marine fish characterized by a deep necrotizing myositis and subdermal hemorrhages. This disease is particularly important when it occurs at fish farms because the economic losses are world-wide and considerable. The main predisposing factor seems to be a rise in water temperature to 15°C or more (Sakazaki and Balows, 1981). *V. anguillarum* may also cause a necrotic disease of bivalve mollusks' larvae and juveniles (Tubiash et al., 1970).

V. anguillarum grows on many bacteriological media if the NaCl content is 1 to 2%, but most strains do not grow well on TCBS agar (Sakazaki and Balows, 1981). BTB teepol agar, originally described for the isolation of *V. parahaemolyticus*, is a good isolation medium for specimens obtained from diseased fish.

BTB-Teepol Agar (Akiyama et al., 1963)

Beef extract	5 g
Peptone	10 g
Sucrose	10 g
Sodium chloride	20 g
Teepol (Shell Chemical Co.)*	2 ml
Bromthymol blue	80 mg
agar	15 g
water	1 liter

Adjust the pH to 7.8. Dissolve the ingredients by gentle heating. Autoclave at 121°C for 15 min, and pour into plates. *V. anguillarum* grows as moderate-sized yellow colonies (Sakazaki and Balows, 1981), but other vibrios also grow, so complete identification will be required for the colonies picked.

*Sakazaki and Balows (1981) indicate that Turgitol 7 may be substituted.

Identification of *V. anguillarum* may be difficult because strains vary considerably in their phenotypic properties (Table 15). Strain from fish disease with this biochemical pattern are likely to be *V. anguillarum*.

Vibrio ordalii

V. ordalii is a halophilic *Vibrio* species that is very closely related to *Vibrio anguillarum* and was named by Schiewe et al. (1981). Previously, other investigators had studied vibriosis of marine fish and isolated a halophilic vibrio similar to, but less biochemically active (Table 15) than *V. anguillarum*. This organism was referred to as "*Vibrio* sp. 1669 group," "*Vibrio* sp. RT group" *Beneckea anguillara* biotype I, or *Vibrio anguillarum* biotype 2. However, the DNA-DNA hybridization studies of Schiewe et al. (1981) indicated that, although it was closely related to *V. anguillarum*, it was a separate species. *V. ordalii* has been isolated from diseased salmonid fish in Washington, Oregon, British Columbia, and Japan reference is not an exact match (Schiewe et al., 1981), and from ayu (*Plecoglossus altivelis*) and rockfish fingerlings (*Sebastes schlegeli*) in Japan (Muroga et al., 1986). The GC content of the DNA is 43–44 mol%.

Vibrio aestuarianus

V. aestuarianus is a halophilic *Vibrio* species that was first described by Tison and Seidler (1983) who isolated it from water and shellfish off the coast of Oregon. Strains are arginine-positive, Voges-Proskauer-negative, sucrose-positive, and lactose-positive, and do not grow in media with 0 or 5% NaCl. The GC content of the DNA is 43–44 mol%.

Vibrio campbellii

V. campbellii is a halophilic *Vibrio* species that was first described by Baumann et al. (1971a)

who isolated 60 strains from ocean water off the coast of Hawaii. They noted considerable variation in the phenotypic properties of this large group, but included all of them in *V. campbellii*. The GC content of the DNA is 46–48 mol%, and this species is about 65% related by DNA-DNA hybridization to *Vibrio harveyi* (Reichelt et al., 1976). Grimes et al. (1986) isolated 20 strains from seawater during a voyage from Barbados to Puerto Rico to Bermuda, and concluded that *V. campbellii* is also found in the open waters of the Atlantic ocean.

Vibrio costicola

V. costicola was first described by Smith (1938). It is a unique *Vibrio* species because of its large requirement for and tolerance to NaCl. Strains usually will not grow in laboratory media unless the NaCl content is 200–250 mM (1.17 to 1.46% NaCl), which defines *V. costicola* as a moderate halophile. Strains have been isolated from environments with a very high salt content, such as meat-curing brines and solar salterns (Garcia et al., 1987). *V. costicola* has been a popular organism in physiological studies, particularly those comparing different halophilic bacteria or comparing halophilic with nonhalophilic species. The GC content of the DNA is 50 mol%.

Vibrio diazotrophicus

V. diazotrophicus is a halophilic *Vibrio* species that was first described by Guerinot and Patriquin (1981), who isolated nitrogen-fixing vibrios from sea urchins (*Strongylocentrotus droebachiensis*) in Nova Scotia. This group of three strains plus 10 additional ones was named *Vibrio diazotrophicus* by Guerinot et al. (1982) because it was not highly related to other vibrios by DNA-DNA hybridization. An additional nitrogen-fixing species isolated from a sea urchin (*Triploneustes ventricosus*) in Barbados was only 14% related by DNA-DNA hybridization, so it was excluded from the species. The ability to fix molecular nitrogen seems to be a unique property for this species of *Vibrio*. Other strains have been isolated from ditch water, sediment, and reeds at Chetney Marsh, England; the Humbler River (England), and Chesapeake Bay water. The GC content of the DNA is 46–47 mol%.

Vibrio fischeri

V. fischeri is a halophilic *Vibrio* species that is also bioluminescent. It was first described as *Photobacterium fischerii* by Beijerinck (1989) and later classified in the genus *Vibrio* by Lehmann and Neumann (1896). It was named for Bernhard Fisher who was one of the first to sys-

tematically study bioluminescent bacteria. Strains grow at 30°C but many can not grow at 37°C. Many strains produce yellow pigment. *V. fischeri* has been isolated from many geographical locations and from coastal and open ocean seawater, surfaces and feces of fish and squids, luminous organs (Baumann and Baumann, 1981), and seafood (Furniss et al., 1978). The GC content of the DNA is 39–41 mol%.

Vibrio gazogenes

V. gazogenes is a halophilic *Vibrio* species that produces a characteristic dry red colony on marine agar that makes it easy to isolate and identify. It was first described as *Beneckea gazogenes* by Harwood (1978), but was reclassified in the genus *Vibrio* when the genus *Beneckea* was abolished. Strains produce gas during fermentation but do not reduce nitrate to nitrite, which also proves very useful in identification. *V. gazogenes* has been isolated from salt marshes in Massachusetts (Harwood, 1978), North Carolina, and South Carolina (Farmer et al., 1988) and from a hypersaline basin at Laguna Figueroa, Baja California de Norte, Mexico (Giovannoni and Margulis, 1981). The GC content of the DNA is 47 mol%.

Vibrio harveyi

V. harveyi is a halophilic *Vibrio* species that was first described as *Achromobacter harveyi* by Johnson and Shunk (1936), who named it for E. N. Harvey, a pioneer in the study of bioluminescence. It has been classified in *Lucibacterium* and *Beneckea*, but is now included in *Vibrio*. Many strains are bioluminescent, but nonluminescent strains occur also and can be difficult to distinguish from other vibrios (Furniss et al., 1978), particularly *V. vulnificus* (Yang et al., 1983). *V. harveyi* has been isolated from many geographical locations and from coastal and open ocean seawater, and surfaces and feces of fish and squids (Baumann and Baumann, 1981). Many papers have been published on its physiology and metabolism, and it is often used in bioluminescence studies. The GC content of the DNA is 46–48 mol%.

Vibrio logei

V. logei is a halophilic *Vibrio* species that was first described as *Photobacterium logei* by reference is not an exact match Bang et al. (1978) who studied a group of strains that had been isolated from a variety of marine sources. Strains of *V. logei* are bioluminescent, yellow-pigmented, and grow at 4 and 15°C, but not at 30°C. Many of the isolates of *V. logei* were obtained in the Arctic, and

sources include exoskeleton lesions of tanner crabs, fish intestinal contents, scallops, and marine sediments (Baumann and Baumann, 1981). The GC content of the DNA is 40–42 mol%.

Vibrio marinus

V. marinus is a halophilic *Vibrio* species that was first described as *Spirillum marinum* by Russell (1891), who isolated it from samples taken in the Gulf of Naples (Ford, 1927; Colwell and Morita, 1964). Colwell and Morita (1964) described 16 strains of *V. marinus* that were isolated from Puget Sound on the Pacific coast of the United States. However, only one strain (ATCC 15381, from seawater) is still available, and there has been limited work on this species. *V. marinus* is a psychrophilic marine vibrio and grows at 4 and 20°C, but not at 30°C (Baumann et al., 1984). The GC content of the DNA is 42 mol%.

Vibrio mediterranei

V. mediterranei is a halophilic *Vibrio* species that was first described by Pujalte and Garay (1986), who isolated it from plankton, sediments, and seawater in two coastal areas south of Valencia, Spain (Pujalte et al., 1983). There are no outstanding characteristics for *V. mediterranei*, so complete biochemical testing is required to distinguish it from other marine vibrios (Table 4). The GC content of the DNA is 42–43 mol%.

Vibrio natriegens

V. natriegens is a halophilic *Vibrio* species that was first described as *Pseudomonas natriegens* by Payne et al. (1961), who isolated it from salt marsh mud on Sapelo Island off the coast of Georgia. *V. natriegens* uses a wider variety of carbon sources than other marine vibrios (Baumann and Baumann, 1984), which make it easy to isolate and identify. It also has the shortest generation time (9.8 min) of any bacterium (Eagon, 1962), which makes it a popular species to use in teaching exercises and physiological studies. *V. natriegens* has been isolated from coastal seawater in several locations (Baumann and Baumann, 1981; Furniss et al., 1978). The GC content of the DNA is 46–47 mol%.

Vibrio nereis

V. nereis is a halophilic *Vibrio* species that was first described as *Beneckea nereida* by Baumann et al. (1971a), who isolated it from seawater off the coast of Oahu, Hawaii. *V. nereis* accumulates PHB is positive for arginine dihydrolase, and does not grow on TCBS agar (Furniss et al.,

1978), but is otherwise similar to other marine vibrios. Kusuda et al. (1986) isolated *V. nereis* from an outbreak of fatal infections of sea bream (*Acanthopagrus schlegeli*) at hatcheries in western Japan, but did not think this organism was actually infecting the fish. The GC content of the DNA is 46–47 mol%.

Vibrio nigripulchritudo

V. nigripulchritudo is a halophilic *Vibrio* species that was first described as *Beneckea nigrapulchritudo* by Baumann et al. (1971b), who isolated it from seawater off the coast of Oahu, Hawaii. Colonies of *V. nigripulchritudo* produce a distinct blue-black pigment which simplifies its isolation and identification. The GC content of the DNA is 46–47 mol%.

Vibrio orientalis

V. orientalis is a halophilic *Vibrio* species that was first described by Yang et al. (1983), who isolated it from seawater and shrimp off the coast of China. No other isolates have been reported in the literature. All the original strains of *V. orientalis* were reported to be bioluminescent, but in our hands strains (which had been freeze-dried) have been weak or negative. Strains of *V. orientalis* grow at 4, 30, and 35°C, accumulate PHB, and are arginine positive. However, it can easily be confused with other marine vibrios (Table 15). The GC content of the DNA is 45–46 mol%.

Vibrio pelagius

V. pelagius is a halophilic *Vibrio* species that was first described as *Beneckea pelagia* by Baumann et al. (1971a) who isolated it from seawater off the coast of Oahu, Hawaii. Few additional isolations have been reported in the literature; however, Furniss et al. (1978) indicate that *V. pelagius* is one of the most common vibrios isolated around the British coasts. This species is subdivided into two groups based on DNA-DNA hybridization and phenotypic properties, and can easily be confused with other marine vibrios. The GC content of the DNA is 45–47 mol%.

Vibrio proteolyticus

V. proteolyticus is a halophilic *Vibrio* species that was first described as *Aeromonas proteolytica* by Merkel et al. (1964), who isolated it from *Limnoria tripunctata* (a small, wood-boring isopod crustacean) collected from wood pilings at Fort Jackson Marine Biological Laboratory, Charleston, South Carolina. This is the only strain described in the literature. This strain of *V. proteolyticus* swarms on complex marine media, is

highly proteolytic and Voges-Proskauer positive, but can easily be confused with other marine vibrios (Table 15). The GC content of the DNA is 50.5 mol%.

Vibrio salmonicida

V. salmonicida is a halophilic *Vibrio* species that causes a serious disease (“Hitra disease” or “cold-water vibriosis”) of Atlantic salmon (*Salmo salar*) and rainbow trout (*Salmo gairdneri*) in Norwegian salmonid farms (Egidius et al., 1981). This organism had a number of vernacular names until it was named *V. salmonicida* by reference is not an exact match Egidius et al. (1986), who showed that it was not closely related to other *Vibrio* species by DNA-DNA hybridization (Wiik and Egidius, 1986). Strain of *V. salmonicida* grow slowly on laboratory media and have a very low growth temperature range of 1–22°C. Its psychrophilic nature, very slow growth rate, and narrow ecological niche are helpful in isolation and identification. The GC content of the DNA is 42 mol%.

Vibrio splendidus

V. splendidus is a halophilic *Vibrio* species that was first described as *Photobacter splendidum* by Beijerinck (1900). This species is subdivided into two groups by DNA-DNA hybridization and phenotypic properties, and can easily be confused with other marine vibrios (Table 15). *V. splendidus* biogroup 1 strains are bioluminescent and positive for arginine dihydrolase, but strains of biogroup 2 are negative for both tests. Strains of *V. splendidus* have been isolated from seawater and fish on the east coast of North America and Denmark (Baumann and Baumann, 1981). The GC content of the DNA is 45–46 mol%.

Vibrio tubiashii

V. tubiashii is a halophilic *Vibrio* species that was first isolated by Tubiash et al. (1965), who was studying bacillary necrotic disease of larval and juvenile bivalve mollusks. These authors identified the causative bacterium as *Vibrio anguillarum* and deposited three strains (ATCC 19105, 19106, and 19109) in the American Type Culture Collection. However, Hada et al. (1984) studied these three strains and showed that they belonged to a new species they named *V. tubiashii*, in honor of H. S. Tubiash. This species does not have any outstanding phenotypic properties to distinguish it from other marine vibrios, but seems to be isolated only from diseased marine mollusks. It is pathogenic for larvae of three oyster species (Hada et al., 1984), *Crassostrea virginica*, *Crassostrea gigas*, and *Ostrea edulis* (Lodeiros et al.,

1987); larvae of the clam *Mercenaria mercenaria* (Hada et al., 1984); and for the lesser octopus *Eledone cirrhosa* (Bullock et al., 1987). The GC content of the DNA is 43–45 mol%.

The Genus *Photobacterium*

The genus name *Photobacterium* was first used by Beijerinck (1889), and for much of its history the genus has been based on a single characteristic, bioluminescence, the ability to produce light. As time passed, nonfermentative and Gram-positive bioluminescent species were removed from the genus, but only in the decade has it had a more narrow definition based on evolutionary relationships (Baumann and Baumann, 1981, 1984). Today, most authorities recognize only three species in the genus: *P. phosphoreum*, *P. leiognathi*, and *P. angustum*. Because other bioluminescent bacteria have been included in the genus *Photobacterium* for so much of its history, it is very difficult to identify the true species. Table 18 lists the differential and other properties of the three *Photobacterium* species.

History, Nomenclature, and Classification

A general discussion of bacterial bioluminescence is given in *The Luminous Bacteria* in the second edition. Bacterial bioluminescence dates back to ancient times, but its bacterial nature has been known for only a hundred years (Sieburth, 1979). Aristotle recorded that dead fish could sometimes produce light, and Robert Boyle noted that air was required for light production. However, it was not until the late 1880s that studies were done on bioluminescent bacteria (ZoBell, 1946).

Luminescent bacteria were isolated from a variety of marine samples by several early bacteriologists, and Pflüger (1875) may have been the first of these (ZoBell, 1946). He isolated luminescent bacteria from fish, but did not name any species. Bernard Fischer, for whom *Photobacterium fischeri* (now *Vibrio fischeri*) is named, served as a ship's physician on the voyage of the S. M. S. *Moltke* from the Baltic Sea to the West Indies and made a number of discoveries in marine microbiology (ZoBell, 1946). He isolated a bioluminescent organism from waters in the West Indies and named it *Photobacterium indicum* (Fischer, 1887).

Over the next hundred years, a large number of bioluminescent bacteria were isolated from different sources, mostly marine. Many of these organisms were given scientific names and classified in the genus *Photobacterium*. *Index Bergeyana* (Buchanan et al., 1966, p. 803–806)

lists over 40 different *Photobacterium* species, and the *Supplement to Index Bergeyana* (Gibbons et al., 1981, p. 201–202) lists an additional 10 species. The original descriptions of most of these organisms are sketchy, but some are probably synonyms of the current *Photobacterium* species or of bioluminescent *Vibrio* species (Baumann and Baumann, 1981).

The genus *Photobacterium* as it is currently defined is based on the studies of Reichelt et al. (1976), who used DNA-DNA hybridization to compare several species of *Photobacterium* and *Vibrio* (Baumann and Baumann, 1981). They examined *P. phosphoreum* strain 404 and found that it was 84% related (at a hybridization temperature of 63°C) to the type strain of this species (strain 439 = ATCC 11040) and 92 to 99% related to three other strains of this species (Fig. 16). *P. phosphoreum* strain 404 was 22–36% related to five strains of *P. angustum*, and 24–36% related to five strains of *P. leiognathi*. However, these latter two *Photobacterium* species were more closely related to *P. phosphoreum* than was *V. harveyi* (11–13%) (called *Beneckea harveyi* in the paper) *V. fischeri* (5–12%), *V. cholerae* (0%), and six other *Vibrio* species (0–5%). The close relatedness of the three *Photobacterium* species is the basis of the genus as it is now defined; however, *P. angustum* and *P. leiognathi* are much more closely related to each other than they are to *P. phosphoreum* (Fig. 16).

In their chapter for the first edition of this handbook, Baumann and Bauman (1981) included *Vibrio fischeri* and *V. logei* (Bang et al., 1978a) in the genus *Photobacterium*, but in the Addendum they reclassified both of these species in the genus *Vibrio*. This latter classification was in better agreement with the morphological, phenotypic, and molecular data.

Description of the Genus *Photobacterium*

The following description now applies to the genus: small, plump, rod-shaped bacteria, Gram-negative, motile with one to three unsheathed polar flagella (Fig. 14, part 5; Fig. 15, parts 11 to 15), usually bioluminescent (two of the three species), accumulate large amounts of PHB when grown in a basal medium with glucose as the sole source of carbon (Fig. 15, part 13), do not form PHB when grown in rich media containing peptone, grow in the presence and absence of oxygen, are oxidase-positive (2 of 3 species) and catalase-positive, reduce nitrate to nitrite, grow with glucose as the sole source of carbon and NH_4^+ as the sole source of nitrogen (some strains require amino acids for growth, see Table 18), require Na^+ for growth, metabolism is fermentative rather than oxidative, and one species produces gas during fermentation.

Table 18. Differential and other properties of the three species of *Photobacterium*.^a

Property or test	<i>P. phosphorium</i>	<i>P. leiognathi</i>	<i>P. angustum</i>

^aThe numbers give the percentage positive for *P. phosphoreum* (74 strains studied) and for *P. leiognathi* (28 strains). Adapted from Reichelt and Baumann (1976).

Habitats

Photobacterium and other bioluminescent bacteria are widely distributed in the marine environ-

ment (Baumann and Baumann, 1981, 1984), and one must be careful to determine which reports are using the terms *Photobacterium* and bioluminescent bacteria interchangeably. Biolumines-

Fig. 16. Relatedness of the three species of *Photobacterium* by DNA-DNA hybridization; note that *P. angustum* and *P. leiognathi* are more closely related to each other than they are to the type species for the genus, *P. phosphoreum*.

cent bacteria are very common in marine water samples, and are presumably shed into the water from more protected ecological niches (Hastings and Nealson, 1977, 1981; see also *The Luminous Bacteria* in the second edition).

In addition to their common occurrence on fish and other marine animals, luminescent bacteria are found in the light organs (Fig. 17) of many marine animals (Bassot, 1975; Boisvert et al., 1967; Harvey, 1940; Hastings and Nealson, 1977, 1981). Two of the species of *Photobacterium* inhabit the light organs of marine fish. *P. phosphoreum* inhabits the light organs of five fish families (Table 18) that are usually found in deep cold waters. This ecological niche agrees with the fact that this species grows at 4°C, but poorly at 25°C and not at 30 or 37°C. *P. phosphoreum* is clearly a psychrophilic deep-water species. Reichelt and Baumann (1973) found it at depths of 50 to 500 off the coast of Hawaii. *P. leiognathi* inhabits the light organs of two fish families (Table 18) that are usually found in warm, shallow, tropical water (Hastings and Nealson, 1981). This species grows at higher temperatures, (Table 18) which agrees with this warmer habitat. In their review of *Photobacterium*, Baumann and Baumann (1984) mention that the only isolates of *P. angustum* have been from the open ocean off Hawaii. However, both *P. angustum* and *V. logei* have been reported recently from a marine fish-rearing unit (Austin, 1983).

Hastings and Nealson (1981) point out that light emission by bioluminescent bacteria may not directly benefit the bacterium, but may be important to its partner in a mutualistic symbiotic relationship. The symbiotic bioluminescent bacteria provide an excellent example of this rela-

tionship where the partner is usually a marine fish. The bacteria are localized in a light organ where they emit light. The review of the symbiotic bioluminescent bacteria by Hastings and Nealson (1981) is highly recommended (see also *The Luminous Bacteria* in the second edition).

Bioluminescent bacteria are very numerous in the intestinal tract of marine fish and often comprise close to 100% of the aerobic heterotrophic flora. They are also found on the gills, and in lower numbers on the skin (Baumann and Baumann, 1981, 1984).

Isolation

Strains of *Photobacterium* and bioluminescent *Vibrio* species can easily be isolated from seawater and marine animals (Baumann and Baumann, 1981; Hastings and Nealson, 1981). The best sources of *P. phosphoreum* and *P. leiognathi* are the luminous organs of marine fish (Table 18), where they are present in high numbers and are often in pure culture.

Seawater or similar marine media are usually required for growth and optimum light production. Luminescence and respiration are reduced in medium when seawater is diluted by more than 50% with fresh water. Isolation of luminescent vibrios has been discussed previously; there are no specific media to select for *Photobacterium* species at the expense of other vibrios.

Identification

The species of *Photobacterium* are phenotypically very similar to the marine species of *Vibrio* (Table 15; also see Table 4 in *The Family*

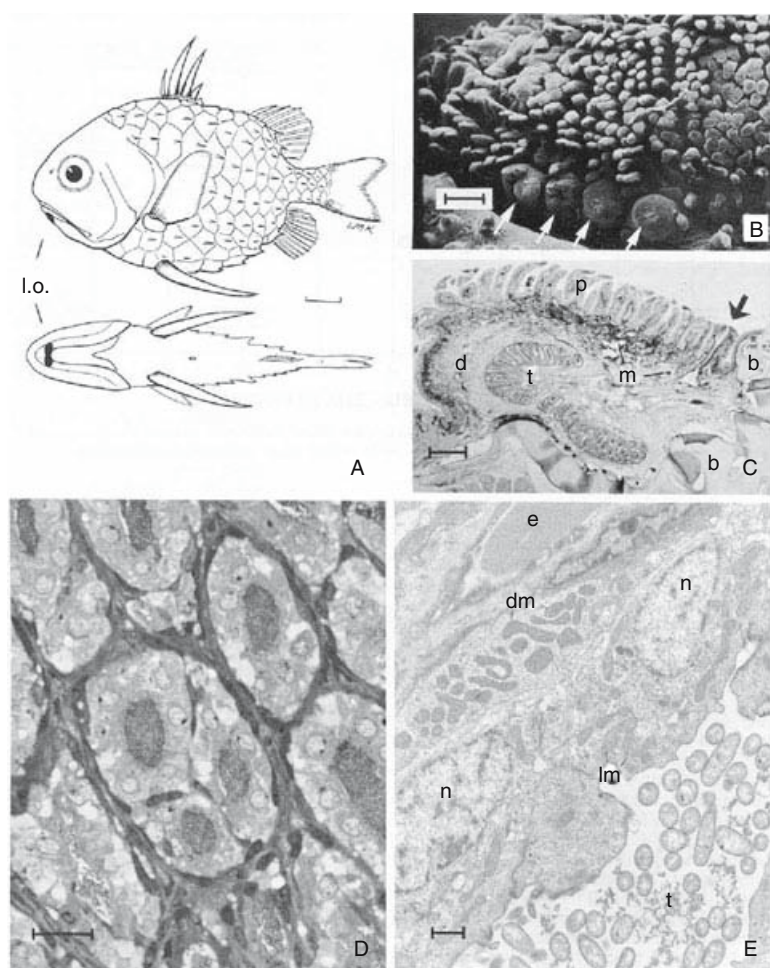

Fig. 17. *Monocentris japonicus*. (A) Line drawing of fish and ventral view of lower jaw, showing location of light organs (l.o.). Bar = 1.0 cm. (B) Scanning electron micrograph of the dorsal surface of the light organ. Numerous dermal papillae can be seen. The emissary ducts from the light organ emerge at the tips of the four large dermal papillae (arrows). Bar = 0.2 mm. (C) Light micrograph of a sagittal section of the lower jaw. m, melanocytes; t, tubules with bacteria; b, mandibular bone; d, dermal layer; p, dermal papillae. Arrow points to emissary duct. Bar = 50 μ m. (D) Light micrograph showing the light organ tubules filled with bacteria. Tubules are lined with a single layer of cuboidal epithelial cells that display loose nuclear chromatin and prominent nucleoli supported by connective tissue cells. Blood capillaries are sparse and not readily visible. Bar = 15 μ m. (E) Electron micrograph showing the major features of tubule epithelium. Epithelial cells that make up the lining of the tubules have light-staining mitochondria (lm) with fine cristae. Epithelial cells that are further away from the tubule lumen next to the blood capillaries have dark-staining mitochondria (dm) with thick cristae. t, tubule containing luminous bacteria; e, erythrocyte visible in capillary; n, nucleus of tubule epithelium cells. Bar = 1 μ m.

Vibrionaceae in this Volume). For this reason it can be difficult to differentiate them (Baumann and Baumann, 1981; Hastings and Nealson, 1981). Samples from the light organs of certain marine fish (Table 18) are likely to yield either *P. phosphoreum* or *P. leiognathi*. Isolates from seawater or decaying organic matter are more difficult to identify to species because they could be one of the *Photobacterium* species or one of the other bioluminescent vibrios. Table 15 gives the biochemical reactions of the three species of *Photobacterium* and the species of *Vibrio* that can be confused with them. Several of the tests require comment.

Biochemical and Other Tests (Baumann and Baumann, 1981; Hastings and Nealson, 1981)

OXIDASE The results for this test are variable for the three species of *Photobacterium*, in contrast to most strains of *Vibrio*, *Aeromonas*, and *Plesiomonas*, which are strongly oxidase-positive. Strains of *Photobacterium* apparently contain

low levels of cytochrome *c*, the compound that is responsible for a positive oxidase reaction. Strains that are oxidase negative should be retested after treating the cells with toluene (Baumann and Baumann, 1981). Toluene treatment presumably causes cell lysis and liberation of internal proteins. Many oxidase-negative strains of *Photobacterium* are positive with this modification.

FLAGELLA STAINS Reichelt et al. (1976) showed that tufts of polar flagella often tended to fold backwards, giving the appearance of peritrichous flagella, especially in Leifson (1960) flagella stains.

ARGININE DIHYDROLASE-DECARBOXYLASE Strains of *Photobacterium* sometimes produce an alkaline reaction in arginine decarboxylase test media, such as Moeller's medium used in clinical microbiology laboratories, even though they lack the enzyme arginine dihydrolase (Baumann and Baumann, 1984). *P. phosphoreum* apparently decarboxylates and deaminates arginine.

NUTRITIONAL REQUIREMENTS These tests may be helpful for identifying *Photobacterium* strains, particularly those that have been maintained in the laboratory. Most freshly isolated strains of *Photobacterium* and other luminescent bacteria do not require vitamins or amino acids (Ruby and Nealson, 1978), but strains that have been maintained in the laboratory may have a requirement (Baumann and Baumann, 1981) (Table 18). Frequent transfers on complex media probably lead to these nutritional defects.

DARK (NONBIOLUMINESCENT) MUTANTS OF BIOLUMINESCENT STRAINS Strains may become nonbioluminescent when they are maintained in the laboratory or in culture collections in contrast to the original strains that are brightly luminescent.

CARBON SOURCES In contrast to most *Vibrio* species that are nutritionally very versatile, the species of *Photobacterium* can use only a few compounds as sources of carbon and energy (Baumann and Baumann, 1981, 1984).

TURNOVER KINETICS OF THE ENZYME LUCIFERASE Hastings and Mitchell (1971) showed that the enzyme luciferase differs in its "turnover kinetics" depending on the bioluminescent species from which it is isolated. The luciferase from *V. harveyi* has slow turnover kinetics, in contrast to the fast turnover kinetics of *V. fischeri* and *P. leiognathi*. At one time this difference was used as a characteristic for differentiating the genus *Photobacterium* from the bioluminescent species of *Vibrio* (Hastings and Nealson, 1981).

Acknowledgments. We thank Paul and Linda Baumann who allowed us to reproduce and adapt text, tables, and figures of *Vibrio* and *Photobacterium* from their chapter, *The Marine Gram-Negative Eubacteria: Genera Photobacterium, Beneckea, Alteromonas, Pseudomonas* and *Alcaligenes* (Baumann and Baumann, 1981), in the first edition of *The Prokaryotes*; J. Woodland Hastings and Kenneth H. Nealson for allowing us to reproduce figures from their chapter, *The Symbiotic Luminous Bacteria* (Hastings and Nealson, 1981), in the first edition of *The Prokaryotes*; and the staff and visiting scientists of the Enteric Bacteriology Laboratories at the Centers for Disease Control who did the phenotypic characterization of strains in our collection.

The Genera *Aeromonas* and *Plesiomonas*

J. J. FARMER III, M. J. ARDUINO AND F. W. HICKMAN-BRENNER

Traditionally the genera *Aeromonas* and *Plesiomonas* have been considered together. Three international workshops (International Workshop, 1986, 1988, 1990) have considered many different aspects of these two genera. In addition, the two genera are usually included in the same chapter or review (von Graevenitz, 1985). Only recently, however, has the relationship of the two genera been studied with methods that measure evolutionary distance. Although *Aeromonas* and *Plesiomonas* are not closely related, we have taken the traditional approach and considered them together in this chapter. However, we have separated most of our discussion because their differences seem more important than their similarities.

The Genus *Aeromonas*

The genus *Aeromonas* has been known to microbiologists for many years. Most of the early literature was about diseases of frogs, fish, and other animals. *Aeromonas* is now recognized as an important opportunistic pathogen of humans; however, there is a controversy on the role of *Aeromonas* as a cause of human diarrhea. Through 1989, there were 1,436 literature citations for *Aeromonas* in the Medline computer data base and 2,589 citations in BIOSIS, so the reader interested in a particular aspect can use a computer literature search as a starting point.

History, Nomenclature, and Classification of *Aeromonas*

The nomenclature and classification of the genus *Aeromonas* has been in a state of flux since these organisms were first described in the early 1890s and it is often difficult to know which *Aeromonas* species (in today's usage) a particular article in the literature deals with. We have divided the history of *Aeromonas* into three different time periods. In the period 1890–1936, many different names were proposed for the *Aeromonas* strains isolated from a wide variety of sources and dis-

eases. In the period 1936–1979, the genus *Aeromonas* as we know it today was established, and many of the described species were studied and compared using techniques that measure phenotypic similarities and differences, but not evolutionary distance. Since 1979, techniques that measure evolutionary distance have been used to compare the species and to determine their relationship to other bacteria. These techniques have yielded some surprising results that form the basis of a more logical classification for the genus *Aeromonas*.

Aeromonas from 1890 to 1936

The first description of an organism that is now known to be an authentic *Aeromonas* species perhaps was that of *Bacillus hydrophilus fuscus* by Sanarelli (1891). Sanarelli (1891) was studying immunity to the anthrax bacillus in frogs, but many of his animals developed a septicemia that was not caused by the anthrax bacillus. Sanarelli isolated the causative bacterium and named it *B. hydrophilus fuscus*.

Other *Aeromonas*-like organisms were also described during this period by workers studying septicemic diseases of frogs (Ernst, 1890; Sanarelli, 1891). Other strains were soon isolated from water (Beijerinck, 1900; Zimmerman, 1890), milk (Hammer, 1917), and diseased trout (Emmerich and Weibel, 1894). The methods used to characterize and identify species during this period were very primitive so it is very difficult to determine if different authors are writing about the same organism. Even in the early literature it was clear that two different groups of *Aeromonas* were being studied. Most of the strains were motile, did not produce a brown diffusible pigment, and grew well at 37°C. Today these strains comprise the *Aeromonas hydrophila* group. Strains of a different group were isolated from diseased fish.

PATHOGENIC *AEROMONAS* STRAINS ISOLATED FROM FISH An organism that Emmerich and Weibel (1894) called “*Bacillus der Forellenseuche*” was isolated from diseased trout in 1894. Since then, similar bacteria have been isolated from furunculosis lesions in fish. These bacteria were referred to by Lehmann and Neumann (1896)

as *Bacterium salmonicida*. This organism was described as being a Gram-negative, nonmotile bacillus that liquefied gelatin and had an optimum growth temperature of 10–15°C. It produced a brown pigment in media containing tyrosine and did not grow at 37°C. Today this organism is known as *Aeromonas salmonicida*, an important fish pathogen. Most classifications of *Aeromonas* have treated *A. salmonicida* as a separated named species, which has been the one stable factor in the many classifications proposed for *Aeromonas*.

EARLY CLASSIFICATIONS OF *AEROMONAS* Prior to 1920, organisms that currently belong to the genus *Aeromonas* were classified in the genera *Bacillus* (Chester, 1901; Sanarelli, 1891; Zimmerman, 1890), *Bacterium* (Hammer, 1917), and *Aerobacter* (Beijerinck, 1900). After 1920, the taxonomy became more confusing. Species were classified in the genera *Proteus* (Bergey et al.,

1923; 1925, 1934; Miles and Halnan, 1937; Pribham, 1933), *Pseudomonas* (Breed et al., 1948; Crawford, 1954; Scherago, 1936, 1937), *Escherichia* (Bergey et al., 1923), *Achromobacter* (Bergey et al., 1925), *Flavobacterium* (Bergey et al., 1934), *Bacterium* (Weldin and Levine, 1923), *Necromonas* (Smith, 1963), *Vibrio*, and *Aeromonas*. Many of the species named are actually synonyms of other species (Table 1). During the early 1920s, other species were described but there was little agreement on classification. In the 1930s, there were other changes in the nomenclature and classification of aeromonads (Bergey et al., 1934; Pribham, 1933a, 1933b), but the main contribution was the first use of the genus name *Aeromonas* (Kluyver and van Niel, 1936).

Aeromonas from 1936 to 1979

The genus name *Aeromonas* was first used by Kluyver and van Niel (1936) in their “natural

Table 1. Synonyms of the species of the genus *Aeromonas*.

^aBecause of space limitations, some of these references are not included in the “Literature Cited,” this chapter; complete citations for some references can be found in Ewing et al. (1961).

^b*B. ranicida* is considered a synonym only in the early literature.

system of classification of bacteria.” They attempted to make a more natural classification that was based on both morphological and physiological characteristics, and attempted to group similar organisms into the same family. However, it took many years to further define the genus *Aeromonas* and for it to be accepted as a genus. During the next 20 years, there was an intensive study of the existing species of *Aeromonas*, and several “new” ones were named. During this period many different classifications were proposed. It was very easy to find one or more phenotypic differences among a group of *Aeromonas* strains, but there was no agreement on how to draw species lines. The sixth edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1948) still did not incorporate *Aeromonas* as a genus, and the species included in the genus today were classified in the genera *Pseudomonas* and *Bacterium*. The genus name *Aeromonas* did not appear in *Bergey's Manual of Determinative Bacteriology* until the seventh edition in 1957 (reference is not an exact match Sniezesko, 1957), and there was little agreement on the number of species in the genus.

THE 1960S AND THE 1970S In the 1960s, there were a number of studies on nomenclature and taxonomy of *Aeromonas*, and it was during this decade that the definition of the genus was stabilized. In 1960, the first of the papers by Eddy suggested that the genus *Aeromonas* be redefined from the description given in the seventh edition of *Bergey's Manual* (Breed et al., 1957). He proposed that the genus should contain only three species: *A. liquefaciens*, *A. salmonicida*, and *A. formicans*. Eddy (1962) and Eddy and Carpenter (1964) disagreed with the proposals of Ewing et al. 1961, and felt that the motile aeromonads could be separated into two species, *A. punctata* and *A. caviae*, based on the production of gas from glucose, acetylmethylcarbinol production, and gluconate oxidation. They further maintained that *A. punctata* should be the type species for the genus *Aeromonas*. They concluded that *A. punctata* was the legitimate designation for both *A. liquefaciens* and *A. hydrophila* and that the name *A. caviae* was the correct name for *A. formicans*.

In the eighth edition of *Bergey's Manual* (Schubert, 1974) the genus *Aeromonas* was described as having three species: *A. hydrophila*, *A. punctata*, and *A. salmonicida*, with *A. hydrophila* as the type species. The descriptions were based on the earlier works by Schubert (1967a, 1967b, 1968, 1969a, 1969b, 1969c).

Aeromonas from 1979 to the Present

During this period, techniques that measure evolutionary distance were first used to study *Aero-*

monas strains. MacInnes et al. 1979 did the first DNA hybridization experiments with *Aeromonas* and concluded that the genus consisted of two main evolutionary lines: “a diverse group of motile aeromonads, and the genetically more homogeneous non-motile aeromonads, comprising the species *Aeromonas salmonicida*.”

Popoff et al. 1981 used DNA-DNA hybridization to study a group of motile *Aeromonas* strains from fish (37 strains), humans (10 strains), frogs (4 strains), and water (1 strain). The strains fell into at least seven different DNA hybridization groups, but several of the groups could be further subdivided on the basis of ΔT_m values. The type strain of *A. hydrophila* was highly related to only two other strains, both isolated from fish. According to the *Bacteriological Code* this small group of three strains belong to the species *A. hydrophila* sensu stricto, (in a strict sense), because a species is defined in terms of its type strain and other closely related strains. Popoff et al. 1981 recognized two additional species, *A. caviae* (referred to as *A. hydrophila* biotype anaerogenes in the paper) and *A. sobria*. The study of Popoff et al. 1981 was the first to fully show the complex nature of the *A. hydrophila* group and to clearly define three of its species. Unfortunately, at least four of the groups defined by DNA hybridization could not be separated by simple phenotypic tests, and all three of the named species were heterogeneous because they contained one or more additional DNA hybridization group.

Fanning et al. 1985 obtained representatives of all the DNA hybridization groups defined by Popoff et al. 1981 and did additional DNA hybridization studies. They confirmed that all strains of *Aeromonas* are more closely related to each other than to species in other families, and found that the motile *Aeromonas* species could be divided into at least 10 different DNA hybridization groups.

Problems in Nomenclature and Classification of *Aeromonas*

There are two main problems in the nomenclature and classification of *Aeromonas*. The first is how best to indicate the divergence of *Aeromonas* from related organisms, a topic discussed in Chapter 156. The second problem concerns the nomenclature and classification of the individual *Aeromonas* species, which has been a confusing subject for many years. Although several studies have clearly indicated the evolutionary divergence of *Aeromonas* strains (MacInnes et al., 1979; Popoff et al., 1981), it has not been possible to find simple tests to define each of the DNA hybridization groups. However, several recent publications have helped to define small groups

of strains that can be differentiated. For example, Hickman-Brenner et al. 1987 defined *A. veronii* to include *Aeromonas* strains that are ornithine-decarboxylase positive and biochemically very similar to *Vibrio cholerae*. In a subsequent study, they named *A. schubertii*, including within this species a small group of strains that did not ferment D-mannitol (Hickman-Brenner et al., 1988). Similar studies are needed to better define all the DNA hybridization groups that have been identified in the motile *Aeromonas* group.

In addition to the problems in classification, there are also several problems in nomenclature. The biggest problem is that the name *Aeromonas caviae*, which is widely used in the literature, is a latter synonym of *Aeromonas punctata* and is thus illegitimate. This problem arose because an error was made in strain designation on the 1980 *Approved Lists of Bacterial Names*. There are several other nomenclatural problems, and a request to the Judicial Commission of the International Committee on Systematic Bacteriology will be needed to resolve them. Several different approaches for reporting strains of *Aeromonas* are given in the section on Identification.

Habitats of *Aeromonas*

Strains of *Aeromonas* occupy a wide variety of ecological niches. Motile strain of the *Aeromonas hydrophila* group cause human extraintestinal infections and have also been implicated as causing diarrhea. They also cause a variety of diseases in both cold-blooded and warm-blooded animals. This group is also widely distributed in water and the environment. Most of the published reports on the *Aeromonas hydrophila* group have not subdivided them into currently recognizable species, and there are only a handful of studies that have differentiated them at the level of DNA hybridization group. In contrast, *A. salmonicida* occupies a limited ecological niche, producing furunculosis and bacteremia in fresh-water fish, particularly trout and salmon.

Human Extraintestinal Infections

The first extraintestinal isolates of *Aeromonas* were reported by Bras et al. 1954 from a case of gas gangrene and independently by Hill et al. 1954 from a case of metastatic myositis. Hill et al. 1954 named their organism *Vibrio jamaicensis* and showed that it produced similar symptoms when pure cultures were ingested into rabbits, pigeons, and other animals. The first isolate from a blood culture was reported by Kjems (1955) soon after these initial reports. Many reports of extraintestinal isolates soon followed.

MENINGITIS *Aeromonas* is a rare cause of meningitis. Ellison and Mostow (1984) could find only five cases of meningitis in the literature when they did a survey in 1984. Two of four patients survived, and the fate of one was not mentioned. They also commented on the possible central nervous system (CNS) involvement in patients with *Aeromonas* bacteremia, and suggested that antibiotics chosen to treat bacteremia should be active against the bacterium and should provide adequate cerebrospinal fluid (CSF) concentrations.

BACTEREMIA *Aeromonas* occasionally causes bacteremia, particularly in immunocompromised individuals. Ellison and Mostow (1984) found fewer than 100 cases of *Aeromonas* bacteremia reported in the literature through 1984. A better estimate of the actual number of cases comes from the Communicable Disease Surveillance Center in England. In 1984 there were 45 cases of *Aeromonas* bacteremia in an unpublished surveillance report from England, Wales, and Ireland, and 13 of these (29%) were fatal cases. Most patients with *Aeromonas* bacteremia-septicemia have impaired host defenses that are usually the result of leukemia, other cancers, or liver disease (Ketover et al., 1973; Slotnick, 1970; von Graevenitz and Mensch, 1968). Bacteremia sometimes follows a wound infection that was originally contaminated with environmental water, or a surgical wound that was infected with *Aeromonas*. Bacteremia can also be primary, and result from intestinal tract colonization. Patients with leukemia or liver impairment are particularly susceptible to infection from the gut via the portal system. This is due to ulceration or mucosal breaks in the gastrointestinal (GI) tract due to toxic drugs or impairment of the hepatic reticuloendothelial system (Ellison and Mostow, 1984). *Aeromonas* bacteremia has also been reported in healthy individuals (Lynch et al., 1981; Scott et al., 1978) and may result from wound infection or gastrointestinal carriage.

Several species of *Aeromonas* have been isolated from blood. Janda and Brenden (1987) found that *A. sobria* predominated in 13 cases). *A. sobria* and *A. hydrophila* (3 of the 13 cases) were usually found in pure culture, but *A. caviae* (4 of 13 cases) was found in mixed culture. They commented that this correlated with the fact that *A. sobria* was generally more invasive for tissue than the other species. Of the newly described species *A. veronii*, *A. schubertii*, and *A. media*, only *A. schubertii* has been isolated from blood. Hickman-Brenner et al. 1988 reported that two of their eight isolates of *A. schubertii* were from blood.

OTHER SITES Strains of *Aeromonas* have been isolated from a wide variety of other infections. The most common source is wound infections, many of which are directly related to exposure to water (Joseph et al., 1979; Rosenthal et al., 1974; Slotnick, 1970; Stephen et al., 1975; von Graevenitz and Mensch, 1968). Numerous infected sites and sources of *Aeromonas* range from an alligator bite (Flandry et al., 1989) to urine.

COMMUNITY-ACQUIRED VERSUS NOSOCOMIAL INFECTIONS Washington (1972) reported that 19 of 27 *Aeromonas* strains were acquired in the community and the other eight were acquired in the hospital. Nine of the community-acquired infections were infected wounds which followed trauma, and eight of these were exposed to soil or water at the time of injury. Hospital-acquired infections due to *Aeromonas* appear to be increasing, but outbreaks are rarely reported. An interesting outbreak reported by Mellersh et al. 1984 involved 19 predominantly immunosuppressed patients who were infected or colonized with *Aeromonas*, three of whom acquired pneumonia.

VIRULENCE FACTORS Much work has been done on possible virulence factors in strains isolated from human patients with diarrhea, but much less has been done on the pathogenesis of extraintestinal infections. Strains of *Aeromonas* do not appear to be particularly virulent compared to other species, since most infections are in immunocompromised individuals. Ketover et al. 1973 concluded that two impor-

tant host defense mechanisms were the presence of specific opsonizing antibody and the bactericidal activity of neutrophils, and that these prevent invasive infections due to *Aeromonas*.

There is species-to-species and strain-to-strain variation in the virulence of *Aeromonas*. This has been shown for fish (reference is not an exact match De Figueiredo et al., 1977; Lallier et al., 1981; Wakabayshi et al., 1981) and mice, and it also appears to be true for humans. Table 2 compares three species of *Aeromonas* and lists some of the factors that have been mentioned as possible virulence factors. Strains of *Aeromonas* are known to make a wide variety of cytotoxins, exoenzymes, and other biologically active molecules. Endotoxin is probably a virulence factor in extraintestinal infections since it can cause a localized Schwartzman reaction and hemorrhagic lesions when injected into mice (Ketover et al., 1973).

Necrotizing hemorrhagic lesions have often been observed in *Aeromonas* infections, and these are probably related to one or more of the hemolysins-cytotoxins that many strains produce (Wretling et al., 1971). Brook et al. 1985 injected strains subcutaneously and found that all nine strains of *A. hydrophila*, but only 3 of 15 strains of *A. sobria* caused abscesses. Many strains also produce an elastase which may be a virulence factor (Ljungh and Wadström, 1985. Janda et al. 1985 found that most of human clinical isolates *A. sobria* were virulent for mice (10^7 cells, intraperitoneal injection) but that none of the *A. caviae* strains were virulent (Table 2).

Table 2. Pathogenic properties of the *Aeromonas hydrophila*, *A. caviae*, and *A. sobria* groups.^a

Human Infections: *Aeromonas* as a Cause of Diarrhea

There is a controversy on the etiological role of *Aeromonas* in diarrhea. Some laboratories routinely search for and report strains of *Aeromonas* as intrinsic enteric pathogens (*Salmonella* and *Shigella* are considered intrinsic enteric pathogens). Other authors are more cautious and warn that only some strains are likely to be pathogenic, a situation similar to that with *Escherichia coli* and *Yersinia enterocolitica*. One clear fact is that strains of *Aeromonas* occur in the feces of people both with and without diarrhea.

History of *Aeromonas* Diarrhea

Environmental and animal isolates of *Aeromonas* date back to the 1890s but the first human isolate reported in the literature was in 1937 (Miles and Halnan, 1937). For many years thereafter there were few reports. Lautrop (1961) reported *Aeromonas* as the predominant organism in the feces of seven patients with acute intestinal problems and assigned a possible etiological role. Rosner (1964) reported a case of diarrhea that yielded *Aeromonas*, and this was probably the first report to give any evidence on the etiological role of *Aeromonas*. Today many authors report *Aeromonas* and assign it an etiological role.

Epidemiology

Much has been written about the epidemiology of *Aeromonas* infections, but the situation is confused because the actual diarrheal disease may not have been caused by *Aeromonas*. Sporadic cases have been frequently reported, but documented outbreaks have been rare or non-existent. Most sporadic cases are community-acquired, although hospital-acquired cases have been reported. In industrialized countries, many cases occur during or just after travel to developing countries. Cases of *Aeromonas* diarrhea have been reported from most countries and are more common in the developing world. However, in Australia and in the state of Iowa there is an unusually high frequency among infants, which may be related to the presence of *Aeromonas* in well water or water-distribution systems. Strains of *Aeromonas* tend to occur more frequently in infants or in adults over 60 years of age (Agger et al., 1985; Burke and Gracey, 1986; Millership et al., 1983). Other risk factors include cancer, liver or biliary tract disease, and impaired immunity (Burke and Gracey, 1986), which are similar to the risk factors for extraintestinal infections due to *Aeromonas*.

SOURCES Most authors emphasize the widespread occurrence of *Aeromonas* in the environment, particularly in recreational and drinking water (Burke and Gracey, 1986; Burke et al., 1984a, 1984b; Millership and Chattopadhyay, 1985; Seidler et al., 1980). Several studies have indicated that most *Aeromonas* strains are isolated from humans during the warm months, when the organism is increasing in the environment. This seems to be true for both intestinal and extraintestinal infections. Food is also a likely source for *Aeromonas*, and food cultures have often been positive. Hunter and Broge (1987) found that 5% of ice cream samples in the United Kingdom were positive, and suggested that this may be due to post-processing contamination. Foods that come in contact with water during processing, such as washed vegetables, are also likely to be contaminated.

Etiological Role in Diarrhea; Possible Pathogenic Mechanisms

HUMAN VOLUNTEERS The most damaging evidence against the etiological role of *Aeromonas* in human diarrhea was from the human volunteer studies of Morgan et al. (1985). Five strains were chosen on the basis of source and production of various suspected virulence factors such as hemolysin, cytotoxin, and enterotoxin (suckling mouse assay, rabbit ileal loop assay, cholera toxin cross-reactive factor). Three of the strains did not cause diarrhea or even colonize the volunteers. Strain 6Y from a healthy person in Bangkok, Thailand, colonized 11 of the 20 volunteers but there was diarrhea in only one, a person who had six unformed stools (with no fecal leucocytes) over 12 hours, with a short period of nausea, vomiting, anorexia, and malaise. He remained afebrile and did not develop a more progressive enteric illness. A biopsy of the small intestine was read as normal histologically. Strain 3647 from a diarrhea case in Perth, Australia, colonized three of 16 volunteers, but did not appear to cause illness. One volunteer had very mild diarrhea, but was culture-negative for the strain of *Aeromonas* that was given. This is probably the most important study that has dealt with the etiological role of *Aeromonas* in human diarrhea.

INFANT (SUCKLING) MOUSE ASSAY Several authors have found positive results in this assay, which was originally used for the heat-stable enterotoxin(s) of *E. coli*. Both viable cells and culture filtrates have been found to be positive (reference is not an exact match Pitaransi et al., 1982).

SERENY TEST This test for tissue invasiveness has been uniformly negative (Johnson and Lior, 1981; Ljungh and Kronevi, 1982; Pitarangsi et al., 1982).

COLONIZATION FACTORS AND HEMAGGLUTINS

Many bacterial species that cause diarrhea produce specific cell adhesins or other factors that allow them to colonize the intestine by attaching to cells of the intestinal mucosa. Agger et al. (1985) listed adhesion as a possible virulence factor for *Aeromonas*, and Daily et al. (1981) thought that pileation was involved. Strains of *Aeromonas* can attach to buccal (cheek) cells, apparently due to fimbriae (Atkinson and Trust, 1980; Daily et al., 1981). Attachment to HEp-2 cells or FL 100 intestinal cells does not appear to involve fimbriae. Strains also can attach to rabbit brush border cells and to red blood cells from a variety of animal species. Strains of *Aeromonas* produce two types of hemagglutins. The soluble hemagglutins are similar in some ways to those produced by *Vibrio cholerae* (Flandry et al., 1989; Notermans et al., 1986) except they lack protease activity. Soluble hemagglutins are produced by *A. hydrophila*, *A. sobria*, and *A. caviae*.

Enterotoxins and Other Toxins

The exact mechanism by which strains of *Aeromonas* cause diarrhea (if they really do) is still unknown. Most of the evidence suggests that strains produce one or more toxins that eventually lead to diarrhea. Other studies suggest an invasive disease similar to *Salmonella* and *Shigella*, but this evidence is less compelling.

There is an extensive literature on the ability of *Aeromonas* to produce "enterotoxins" and other toxins. Much confusion has resulted because a single strain can produce several different proteins with biological activity. For example, most strains are hemolytic, and the hemolysin(s) produced during growth are toxic for animals and for animal cells grown in tissue culture. Strains have been reported incorrectly as enterotoxin producers based on the biological effects of these hemolysins. This type of error has been most common when a large number of strains has been screened in several different biological assays. The situation has been clarified by a more detailed study of a limited number of strains, and by subsequent purification and testing of the toxins produced (Chakraborty et al., 1984).

ENTEROTOXINS SIMILAR TO THOSE OF *E. COLI*

Many of the *Aeromonas* studies have utilized assays that were originally defined to study the enterotoxins of *E. coli*. Many of these assays

have been positive, but results from DNA probes now clearly indicate that there is no homology of *Aeromonas* with natural DNA probes for the heat-labile (LT^P) and heat-stable enterotoxins (ST^P and ST^h) of *E. coli* (Pitarangsi et al., 1982).

CHOLERA TOXIN Some strains of *Aeromonas* produce a protein that is similar to cholera toxin. James et al. (1982) noticed the immunological cross-reactivity of their *Aeromonas* toxin and cholera toxin. Some strains of *Aeromonas* produce a protein that reacts in an ELISA assay (Chopra et al., 1986) or a commercial latex agglutination assay (Shimada et al., 1984) for cholera toxin. Schultz and McCardell (1988) found that nine of 12 *Aeromonas* strains reacted with an oligonucleotide-DNA probe for the A and B subunits of cholera toxin. This toxin was positive in the Y1 and CHO tissue culture assays and was heat stable. In immunoblots, the toxin appeared as three different bands with molecular weights of 89,900 (suspected to be the holotoxin), 37,000 (slightly larger than the A or A1 subunit of cholera toxin), and 11,000 (probably the B subunit). When the *Aeromonas* protein was incubated with antibody to cholera toxin, there was a 10-fold reduction in activity, and in an ELISA assay for cholera toxin, readings were equivalent to 3.5 to 100 mg of cholera toxin. The role of this cholera-like toxin in human diarrhea is unclear.

TETRODOTOXIN Tetrodotoxin is a potent neurotoxin that is produced by a variety of marine and land animals. Simidu et al. 1987 showed that a number of *Vibrio* and *Aeromonas* species appeared to produce tetrodotoxin or anhydrotetrodotoxin (a slightly different form of the toxin), and similar results were found by Tamplin et al. (1987). This new toxin is another potential virulence factor or cofactor.

HEMOLYSINS The hemolysin(s) produced by *Aeromonas* are potent toxins. Wretling et al. (1971) purified two different hemolysins from an isolate of *A. hydrophila* and showed they had different isoelectric points. Both hemolysins were cytotoxic to HeLa and human fibroblast cells; lethal for mice; and caused dermonecrosis in rabbits. These biological activities would interfere with a number of enterotoxin assays. However, the hemolysins were destroyed by heating for 10 minutes at 56°C. Asao et al. (1984) found that 93% of *A. hydrophila* and 63% of *A. sobria* strains produced hemolysin that had cytotoxic and enterotoxic activity (positive reaction in the rabbit ileal loop). These results indicate that untreated supernatants of *Aeromonas* cultures will react in a variety of enterotoxin assays because hemolysin(s) is present.

HEAT-STABLE, CYTOTONIC ENTEROTOXIN This protein has been studied by several investigators, and it was recently cloned (Chakraborty et al., 1984). These authors found that two strains of *Aeromonas* from diarrhea patients in India had cytotoxic and hemolytic activity as well as enterotoxic activity. They cloned the enterotoxin gene of *Aeromonas* into *E. coli* and showed that the *E. coli* gene product caused elongation of CHO tissue culture cells and caused fluid accumulation in the rabbit ileal loop model and infant mouse model. Similar cloning experiments indicated that gene products of the hemolysin and cytotoxin genes were negative for fluid accumulation and that these three biological activities were located on three separate parts of the *Aeromonas* chromosome. They concluded that their toxin was a relatively heat-stable, cytotoxic enterotoxin clearly distinct from *E. coli* LT and ST and from hemolysin and cytotoxin.

Does *Aeromonas* Cause Human Diarrhea?

Burke and Gracey (1986) summarized the role of *Aeromonas* in human diarrhea by saying:

Present evidence suggests that *Aeromonas* spp. are potential enteric pathogens with the risk of infection varying with age and geographical location but there remains the possibility that aeromonads could appear in diarrhoeal stools without being the aetiological agent. . . .

This is a good assessment of the evidence concerning *Aeromonas*, but it is also clear from the literature that many authors think that *Aeromonas* is an enteric pathogen. At present it seems clear that some strains of *Aeromonas* can cause diarrhea in some people. In a human volunteer study only one of five strains caused any diarrheal symptoms, and it caused a mild diarrhea in only one of 24 healthy human volunteers. A diarrheal disease is a function of both the host and the microbe. Future studies on the role of *Aeromonas* in diarrhea should focus on both these factors.

Aeromonas Diseases of Animals

Both the *A. hydrophila* group and *A. salmonicida* are important causes of animal diseases. *A. salmonicida* is well known as a fish pathogen and the *A. hydrophila* group causes disease in fish, frogs, and several other animals.

Furunculosis Caused by *A. salmonicida*

Furunculosis caused by *A. salmonicida* is a very important disease because it causes large economic losses of salmon and trout at commercial fish farms. Furunculosis is a communicable sep-

ticemic disease that is found in two different forms (McCarthy, 1977). In the acute form, there are few if any external signs, but there is a sudden onset and a high mortality. In the subacute form there are prominent focal muscle lesion or furuncles (hence the name furunculosis).

The disease has an extensive host range, but fish in the family Salmonida (which includes salmon and trout) are most susceptible, particularly brook trout and Atlantic salmon. Other fish that are affected either in the wild or on fish farms include cutthroat trout, Rocky Mountain white fish, brown trout, "sakuramasu" (*Onco-rhynchus gorbusha*), and many others.

The origin of the disease has been difficult to trace. Some authorities believe it was introduced into Europe in the 1880s with the import of rainbow trout, but others think it originated in Europe and was introduced to America with the brown trout (McCarthy, 1977). It was first introduced into the United Kingdom in 1911, and today it is found worldwide.

The disease is usually found in epidemic form (epizootic) rather than as isolated cases. It is more common in summer months as the water temperature rises. At fish farms it tends to be found where there is misuse of intensive rearing methods, usually by inexperienced personnel (McCarthy, 1977). This leads to stressed fish that are living under suboptimum environmental conditions.

A number of different names have been given to the "*Aeromonas*-like" organisms that have been isolated from fish with the disease. These include "Bacillus devorans" (Zimmerman, 1890), "Bacillus der Forellenseuche," *Bacterium salmonicida* (Emmerich and Weibel, 1894), *Bacterium devorans* (Zimmerman, 1890), *Haemophilus piscum* (Snieszko, 1964) *Necromonas* (Smith, 1963), *Necromonas achromogenes* (Smith, 1963), *A. salmonicida*, *A. salmonicida* subspecies *salmonicida*, and *A. salmonicida* subspecies *masoucida*. All of the earlier names are considered to be synonyms of *A. salmonicida*. Since the named subspecies of *A. salmonicida* are all highly related by DNA-DNA hybridization, it is clear that *A. salmonicida* is a species with variation in its phenotypic properties and host range in fish. There is little need therefore for maintaining three named subspecies.

Diseases Caused by the *Aeromonas hydrophila* Group

In contrast to *A. salmonicida*, which primarily causes furunculosis in salmonid fish, species in the *A. hydrophila* group cause a wide variety of animal diseases, and are widespread in the environment, particularly water.

RED LEG AND OTHER DISEASES OF FROGS Red leg is an important disease because of the wide spread use of frogs in the laboratory. This septicemic disease in frogs is known as red leg because there are characteristic hemorrhages in the muscles of the legs (and abdomen) that cause the legs to have a distinctive red color (Russell, 1898). *A. hydrophila* has often been associated with outbreaks of this disease in frogs (Russell, 1898), particularly in laboratory populations (Gibbs, 1973).

DISEASES OF FISH The *A. hydrophila* group is also important in fish diseases, and can cause dramatic epidemics. Miller and Chapman (1976) reported 37,500 fish deaths during a 13-day period in one North Carolina lake. There have been similar reports for inland eutropic lakes (Hazen et al., 1978b; Shotts et al., 1972). One of the most commonly reported diseases is red sore disease of bass. However, other fish species can be affected including carp, cod (ulcer disease) (Larsen and Jensen, 1977), channel catfish (de Figueriedo and Plumb, 1977), shad (Haley et al., 1967), and centrarchid fish (Esch et al., 1976). Strains of the *A. hydrophila* group are almost always recovered from fish tissues, but the role of other microorganisms such as viruses and protozoa (Esch et al., 1976) must also be considered.

OTHER ANIMAL DISEASES There have been reports of other animal diseases, both in the wild and in laboratory populations. The first report of *A. caviae* (named *Pseudomonas caviae* in the original report) was by Scherago (1936, 1937) who described an outbreak of fatal septicemia in guinea pigs. The animals had been obtained in March 1935 from a local breeder and kept in the laboratory. Within a week, all 16 of the animals were dead. *A. caviae* was isolated from many tissues including liver, spleen, kidney, lung, and heart. The organism also caused a similar fatal infection in white mice but not in rabbits (Scherago, 1937).

Several other literature reports describe various aeromonads in animal diseases. These include "enterotoxin-producing" strains of *A. hydrophila* in piglet diarrhea (Dobrescu, 1978); ulcerative dermatitis and pneumonia associated with *A. hydrophila* in a bottle-nosed dolphin (Cusick and Bullock, 1973); hemorrhagic bacteremia in captive snakes that was transmitted by snakes mites (Camin, 1948); ulcerative stomatitis in captive snakes and lizards (Marcus, 1971); necrotic stomatitis in the desert tortoise (*Gopherus agassizi*) that develop pneumonia (Stroud et al., 1973); epidemic septicemia in reptiles at a zoo (Esterabadi et al., 1973; Heywood, 1968); eye infections and respiratory involve-

ment in laboratory lizards (Cooper et al., 1980); mortality in alligators (*Alligator mississippiensis*) in lakes and ponds where red sore disease was occurring in the fish population (Gorden et al., 1979); cutaneous ulcerations and septicemia in the aquatic African clawed frog *Xenopus laevis*; diarrhea and various other infections in birds (the etiology was not always investigated) (Panigrahy et al., 1981; Shane and Gifford, 1985; Shane et al., 1984); epidemic septicemia in commercial turkeys (Gerlach and Bitzer, 1971); various infections in animals raised for their fur such as mink, seals, and the blue fox (Dahle and Nordsoga, 1968); polyarthritis (Love and Love, 1984) and abortion (Wohlgemuth, 1972) in cows; septicemia in a dog (Pierce et al., 1973); and focal hepatic necrosis in young ferrets (Hiruma et al., 1986). The etiological role of *Aeromonas* was likely in many of these reports, but was less convincing or not investigated in some of the others.

***Aeromonas* in Water and the Environment**

Strains of *Aeromonas* have been isolated from a wide variety of water samples, and it is clear that members of this genus are primarily aquatic organisms. Many cases of infection or colonization in humans and animals can be traced to an exposure to water. In developing countries, people often drink untreated water, which may help to explain the frequent occurrence of *Aeromonas* in feces of people both with or without diarrhea. Many studies have focused on the distribution of *Aeromonas* in water and have tried to correlate a variety water chemistry parameters with counts of *Aeromonas* (Hazen et al., 1978b; Schubert, 1974).

Natural Waters

Schubert (1967c) concluded that most of the *Aeromonas* strains in environmental water were not from human feces but represented the natural habitat of the organism. One of the largest surveys on the distribution of *Aeromonas* in water was done by Hazen et al. (1978b) in the United States. They sampled 147 natural aquatic habitats in 30 states and Puerto Rico and found that most were positive for *Aeromonas*. A few samples were negative, including water with a very high salinity (such as the Great Salt Lake), geothermal springs (45°C or higher temperatures), and three extremely polluted rivers. Of 147 samples, 135 were positive, including a wide variety of different habitats that varied in salinity, conductivity, temperature, pH, and turbidity. Saltwater samples had higher *Aeromonas* counts (a mean value of 746 organisms per ml)

than freshwater samples (a mean value of 130 organisms per ml), and lotic (rapidly moving) environments generally had higher counts than lentic (static) environments (mean values of 161 per ml versus 20 per ml). The highest count was 9,000 *Aeromonas* per ml at New Haven Harbor, Connecticut, a marine habitat with a salinity of 23 parts per thousand. Other samples with over 1,000 per ml included two creeks and two rivers. Although *Aeromonas* is not considered to be an obligate marine bacterium, the highest counts were found where marine ecosystems interface with fresh water, and it was found at all salinities except the most extreme (100% sea water). Similar results were found in Thailand, where 17 of 23 canals (klongs) were positive for *Aeromonas* (Pitarangsi et al., 1982). Versteegh et al. (International Workshop, 1986) studied the distribution of *Aeromonas* in different types of water. Spring water at its source and unpolluted ocean water were negative or had very low counts (2 per 100 ml), but flowing water further from its origin had much larger counts (400 to 1,000 per ml) which was probably due to sewage contamination. Recreational lakes had intermediate counts (10 to 100 per ml). Hazen and Fliermans (1979) studied the distribution of *Aeromonas* in a thermal gradient of effluent canal water at three nuclear reactors at the Savannah River Plant near Aiken, South Carolina. The highest number were found in water at temperatures of 21 to 33°C and none were found at temperatures higher than 45°C. These data are consistent with laboratory studies on the growth of *Aeromonas* in relation to temperature.

Sediment samples usually have much higher counts than the water column. In the Anacostia River near Washington, D.C., Seidler et al. (1980) found that sediment contained up to 400,000 *Aeromonas* per gram compared to 100–300 per ml in the water column. However, in a water reservoir used for cooling at a nuclear reactor, Hazen (1979) found higher counts in the water column than in the sediment. Higher counts are usually present where there is a high concentration of particulate or dissolved organic matter (Hazen, 1979). The counts of *Aeromonas* in environmental water increased as the temperature rose and dropped dramatically during winter (Seidler et al., 1980). *Aeromonas* counts were also high in sewage, and in household and industrial effluents, which may be important sources of *Aeromonas* in the environment.

DRINKING WATER *Aeromonas* is often found in drinking water (Meeks, 1963; Schubert, 1967c) and consequently in sinks, tubes, drain pipes, and household effluents (Schubert, 1967c). Well

water in both developing and industrialized countries also contains *Aeromonas* (von Graevenitz and Mensch, 1968). reference is not an exact match Pitaransi et al. 1982 found that 15 of 15 water jugs (ongs) in Thailand were positive for *Aeromonas*. In one case, water from an artesian well contaminated chicken carcasses as they were being washed (Eddy, 1960). The frequent presence of *Aeromonas* in drinking water must be considered in all studies that attempt to define its role as an enteric pathogen.

HOSPITAL ENVIRONMENT Washington (1972) rarely found *Aeromonas* in hospital environmental surveys. However, Rafferty and Pancoast (1984) noted *Aeromonas* contamination on bedpans, toilet flush handles, telephones, and dictaphones. The contamination was very light and was thought to be of little significance. *Aeromonas* has also been found in the hospital water supply (Meeks, 1963; Conn, 1964), and even in chlorinated hospital water (Millership and Chatopadhyay, 1985). It was found in 71% of the samples that contained *E. coli* and 19% of those that did not contain *E. coli* (Millership and Chatopadhyay, 1985).

OTHER AQUATIC SAMPLES *Aeromonas* has been isolated from raw sewage, treated sewage, activated sludge (Neilson 1978), the mud of sink siphons in waste water drainage systems (Schubert, 1967c), swimming pools (von Graevenitz and Mensch, 1968), and many other aquatic samples.

OTHER SAMPLES Decomposing plant material and fecal material from animals usually contain large numbers (Hazen, 1979). Sanyal et al. 1987 found *Aeromonas* in 98 of the 100 tropical aquaria sampled.

THE COLIFORM CONCEPT—CONFUSION WITH *E. COLI* Some strains of *Aeromonas* ferment lactose at 37°C with the production of gas. For this reason they can be considered to be “coliforms,” and thus can be an important source of error in measuring the bacteriological quality of water. Leclerc and Buttiaux (1962) found that 30% of 9,036 drinking water samples were positive for “fecal-coliform” positive strains of *Aeromonas*, and if further testing had not been done these would have falsely indicated that the sample was positive in the fecal coliform test. A positive-oxidase test easily differentiates *Aeromonas* from *E. coli*, as would the more specific fecal-coliform test in many instances. The widespread distribution of *Aeromonas* in both drinking and environmental water must be considered in bacteriological analysis.

DISTRIBUTION OF *AEROMONAS* SPECIES IN WATER Most studies have not differentiated the *Aeromonas* species or DNA hybridization groups. However, Versteegh et al. (International Workshop, 1986) concluded that *A. hydrophila* predominates in spring water, with about 80% positive. *A. caviae* predominates in marine samples with about 60% positive. *A. sobria* predominates in recreational lakes with about 50% positive. All three species are found in flowing water polluted with sewage.

Isolation of *Aeromonas*

The *A. hydrophila* group occurs in a wide variety of human clinical and environmental specimens, and most strains grow well at 35–37°C as well as 20–25°C. Much of the literature on *Aeromonas* isolation is about this mesophilic group. In contrast, *A. salmonicida* does not grow at 37°C and is usually found only in diseased fish.

Isolation of *A. salmonicida*

Swabs of the fish surface, lesions, or tissue removed at autopsy can be streaked on nutrient agar containing 0.1% tyrosine or phenylalanine, and incubated at 22°C. Strains of *A. salmonicida* grow at this temperature and most typical strains produce a soluble brown pigment.

Isolation of the *A. hydrophila* Group

Some authors feel that *Aeromonas* is an enteric pathogen, and that a selective medium should be incorporated for the isolation of all strains, as is done for *Salmonella* and *Shigella*. We and others feel that only certain strains of *Aeromonas* are pathogens, and that the use of selective media is not indicated because small numbers of *Aeromonas* would be isolated. These strains presumably would not be enteric pathogens, but would probably represent transient gut colonization or merely the passage of organisms ingested from food or drinking water. Both approaches are described below, and the reader is encouraged to use the approach that best fits the laboratory's particular needs. Most isolation procedures used in the clinical microbiology laboratory for extraintestinal specimens should be effective in isolating *Aeromonas* since it grows well on most plating media.

BLOOD AGAR Most extraintestinal specimens are plated on blood agar, and this medium is also recommended for intestinal (stool) specimens. Colonies of *Aeromonas* are 2–3 mm in diameter after 24 h at 35–37°C and many strains are hemolytic. Individual colonies can be tested

for their oxidase reaction (Kovacs method). Oxidase-positive hemolytic colonies (that do not have the characteristic color and odor of *Pseudomonas aeruginosa*) are more likely to be *Aeromonas* than other species. A sweep of several hundred colonies can also be done to detect oxidase-positive colonies mixed with oxidase-negative colonies. If the sweep is oxidase-positive (either weakly or strongly), individual colonies can then be tested (Janda et al., 1984b).

MACCONKEY AGAR Almost all strains grow on MacConkey agar and most grow on SS agar (Nygaard et al., 1970). Different strains of *Aeromonas* can vary in appearance on this medium from bright red with precipitated bile around the colony (indistinguishable from *E. coli*) to light pink to colorless. This is because strains of *Aeromonas* vary in the speed and degree of lactose fermentation. Many strains produce colorless (lactose-negative) colonies and probably would be picked as suspect *Salmonella* or *Shigella*.

OTHER PLATING MEDIA Two other plating media often used for fecal cultures are somewhat selective for *Aeromonas* even though they were designed for the isolation of other organisms. CIN medium (cefsulodin, irgasan, novobiocin) for *Yersinia* isolation is routinely used in many laboratories and will often select for *Aeromonas* (International Workshop, 1986). Similarly, Misra et al. (1989) showed that *Aeromonas* was often isolated on Butzler's *Campylobacter* selective agar. This medium was compared with sheep blood agar containing 30 ug of ampicillin per ml for the isolation of *Aeromonas* from diarrheal stool cultures. Twenty-six of the specimens were positive for *Aeromonas* on both media; 29.6% were positive on Butzler's *Campylobacter* agar only and 43.7% were present only on blood agar plus ampicillin. Other selective media for *Campylobacter* (Skirrow's formulation and Blazer's) contain trimethoprim and polymyxin B and are not suitable for *Aeromonas* isolation because most strains are inhibited by these agents.

Special Media For *Aeromonas*

A number of different media have been described for the isolation of *Aeromonas*, and there have been several evaluations and reviews (von Graevenitz and Bucher, 1983). There is some confusion in the literature on the value of the many *Aeromonas* media, probably due to differences in the populations tested and the fact that different *Aeromonas* species and DNA hybridization groups have been used. We will describe in detail only those media that have been used frequently or that are commercially available.

Bile Salts-Brilliant Green Agar for *Aeromonas* and *Plesiomonas*

Most media were designed to isolate either *Aeromonas* or *Plesiomonas*; one exception is bile salts-brilliant green agar, which was formulated to select for both genera. This medium was described by Millership and Chattopadhyay (1984). It contains bile salts and brilliant green, which should inhibit many enteric and other bacteria.

Nutrient broth no. 2 (Oxoid)	25 g
Bile salts	5 g
Brilliant green, 0.05% solution	1 ml
Agar	12 g
Water	1 liter

Adjust the pH to 7.0. Dissolve all the ingredients by heating to boiling; do not autoclave. Cool to 45–50°C and pour into plates. Streak the specimen onto the plate and incubate at 37°C for 18 h. Flood the plate with oxidase reagent and immediately pick and subculture oxidase-positive (purple) colonies, and further identify them.

Dextrin-Fuchsin-Sulfite Medium (*Aeromonas* Differential Agar)

This medium is one of the first isolation media for *Aeromonas*, and it was originally described by Schubert (1967a, 1967b). It contains dextrin which is metabolized by *Aeromonas* but not by most other enteric bacteria except *Enterobacter*. Dextrin catabolism is indicated by an aldehyde formed with fuchsin which has been reduced by sulfite. This latter reaction is known as the “Endo principle” and has occasionally been used in the formulation of enteric media. The medium can be modified by the addition of various compounds to inhibit Gram-positive organisms and can also be used to isolate *Enterobacter agglomerans* (Bucher and von Graevenitz, 1982).

The following formula is the one given by E. Merck, Darmstadt, Germany, which at one time produced and sold this medium as “*Aeromonas* Differential Agar,” catalog no. 15105.

Peptone (from casein)	10 g
Meat extract	3 g
Sodium chloride	5 g
Dextrin	15 g
Sodium sulfite	1.6 g
Fuchsin	0.25 g
Sodium phosphate (Na ₂ HPO ₄)	7.75 g
Agar	13 g
Water	1 liter

Adjust the pH to 7.5 ± 0.2. Suspend the ingredients in the water and boil until they dissolve completely. (Merck indicates that it may be helpful to first suspend them in 50 ml of a 5% aqueous solution of dioxane to better dissolve the fuchsin.) Autoclave at 121°C for 15 min. Cool to 45–50°C and pour into plates.

Inoculate the specimen onto the medium, and incubate at either 30 or 37°C. Further incubation may be required and should be done at room temperature. Colonies of *Aeromonas* are moist and red because they metabolize the dextrin. Colonies of most species of Enterobacteriaceae and *Pseudomonas* do not metabolize the dextrin and are colorless. Some strains of *Enterobacter* and *Klebsiella* metabolize dextrin and also form red colonies, but they can be differentiated after subculture and oxidase testing. (The manufacturer says that the plate can be sprayed with or flooded with oxidase reagent to detect

oxidase-positive colonies.) Suspicious red colonies are picked and further identified. The manufacturer says that the vibriostatic compound 0129 can be added to the medium to inhibit *Vibrio* species.

Rimler-Shotts Medium

This medium (Shotts and Rimler, 1973) was designed for the isolation of *Aeromonas* from water and animals. It contains novobiocin and deoxycholate to inhibit Gram-positive organisms and vibrios. It contains maltose, which is almost always fermented by *Aeromonas*, and the pH indicator bromthymol blue. It contains L-lysine and L-ornithine which are often decarboxylated by enteric bacterial to give alkaline products (in 1973 *Aeromonas* was thought to be arginine-positive, but lysine-negative and ornithine-negative). It also contained thiosulfate and a ferric salt to indicate H₂S production by organisms such as *Citrobacter*. This medium has been used in a number of studies on the distribution of *Aeromonas* in the environment.

L-Lysine hydrochloride	5 g
L-Ornithine hydrochloride	6.5 g
Maltose	3.5 g
Sodium thiosulfate	6.8 g
L-Cysteine hydrochloride	0.3 g
Bromthymol blue	0.03 g
Ferric ammonium citrate	0.8 g
Sodium deoxycholate	1.0 g
Novobiocin	0.005 g
Yeast extract	3 g
Sodium chloride	5 g
Agar	13.5 g
Water	to 1 liter

Suspend all of the ingredients in the water and adjust the pH to 7.0. Heat to boiling and boil gently for 1 min. Cool to 45°C and pour into petri dishes. Refrigerate until used.

Plate the sample onto the medium and streak to obtain isolated colonies. Incubate at 37°C and observe after 20 h but no later than 24 h. Typical strains of *Aeromonas* are yellow (maltose-positive) without a black center. Other enteric bacteria had a variety of other appearances.

We suspect that lysine-positive and ornithine-positive strains of *Aeromonas* may not have the typical strong yellow color because of alkaline products produced during decarboxylation of the amino acid.

***Aeromonas* Agar**

This is one of the few media for the isolation of *Aeromonas* that is commercially available in a complete form. It contains sodium deoxycholate to inhibit Gram-positive organisms and sodium citrate to inhibit other enteric bacteria. D-Xylose is present as a differential sugar. Most *Aeromonas* strains do not ferment this sugar. Sodium thiosulfate and ferric citrate are included to indicate H₂S production.

<i>Aeromonas</i> agar base (see below)*	47 g
Water	100 ml

pH 7.0 ± 0.2 at 25°

*Also available as a dehydrated powder from Gibco; catalog no. 152-0149M.

Formula for *Aeromonas* agar base:

Peptone 140 (pancreatic digest of casein)	5 g
Beef extract	5 g

D-Xylose	10 g
Sodium chloride	2.5 g
Ferric ammonium citrate	1 g
Sodium citrate	5 g
Sodium deoxycholate	1.5 g
Sodium thiosulfate	5 g
Neutral red	0.025 g
Agar	12 g

Suspend the powder in the water. Heat to boiling to dissolve. Allow to simmer for 20 seconds. Do not autoclave or overheat. Cool to 45–50°C and pour onto plates.

Inoculate the specimen onto the medium and streak to get isolated colonies. Examine the plate and pick xylose-negative colonies as suspect *Aeromonas* for further testing. An alternative is to enrich the specimen in alkaline peptone water first, and then plate it onto the *Aeromonas* agar. Colonies of *Aeromonas* appear as moist pale or colorless colonies about 2 mm in diameter. Strains of *A. sobria* have a slight golden sheen when growth is confluent.

Blood Agar Plus Ampicillin

Most strains of *Aeromonas* from clinical specimens are resistant to 10–30 µg of ampicillin; this led to the formulation of this medium which has often been used in clinical microbiology laboratories. Some *Aeromonas* strains will be inhibited by this concentration of ampicillin, but the majority will grow.

Trypticase soy agar*	40 g
Water	950 ml
Sheep blood	50 ml
Ampicillin**	10 mg

*Other blood agar bases can also be used.

**Other concentrations of ampicillin have been used, including 15 µg/ml (Agger, 1986) and 30 µg/ml.

Suspend the trypticase soy agar in the water and heat to boiling to dissolve. Autoclave at 121°C for 15 min. Cool to 45–50 °C and add the sheep blood and the ampicillin, and pour into plates. Store in the refrigerator in sealed bags until needed. Strains of *Aeromonas* will usually grow and be strongly beta-hemolytic on this medium. Suspicious colonies can be tested for their oxidase reaction.

Prepared plates are available from Remel and contain 10 µg/ml of ampicillin (catalog no. 01–226).

DNase Agar Plus Ampicillin and Toluidine Blue

von Graevenitz and Zinterhofer (1970) described this medium for the isolation of *Aeromonas*. They added ampicillin and toluidine blue to DNase test agar, which is commercially available, and found the medium useful in isolating *Aeromonas* from stool cultures. It should also be useful for other types of specimens.

DNase test medium	42 g
Toluidine blue solution (1%)	10 ml
Water	990 ml
Ampicillin	30 mg

Suspend the DNase test medium in the water. Add the toluidine blue solution. Heat to boiling to dissolve the agar. Autoclave at 121°C for 15 min and cool to 45°C. Aseptically add a solution of ampicillin to give a total of 30 mg. Pour into petri dishes; let cool and store in the refrigerator.

Streak a plate with the sample to obtain isolated colonies. Incubate at 35–37°C for 16–24 h, and look for typical colonies. Colonies of *Aeromonas* grow on the medium and have a large pink zone around them because of DNA hydrolysis. Strains of Enterobacteriaceae that normally occur in feces are usually inhibited or are DNase-negative.

MacConkey Agar Plus Ampicillin and Tween-80

This medium is made by adding ampicillin and Tween-80 to MacConkey agar, and is commercially available in plates from Remel (catalog no. 01–560). Strains of *Aeromonas* hydrolyze Tween-80 and have an opaque zone around them. Most Enterobacteriaceae are inhibited or are negative for Tween-80-hydrolysis.

Pril-Xylose-Ampicillin Agar

This medium was described in 1978 by Rogol et al. (1979) and contains ampicillin and pril (a quaternary ammonium detergent) to inhibit Gram-positive and other enteric bacteria. It contains D-xylose, which is not fermented by most strains of *Aeromonas*, which produce colorless colonies. The medium also prevents swarming of *Proteus* strains.

Nutrient agar	8 g
D-Xylose	10 g
Phenol red	0.025 g
Ampicillin	30 mg
Pril*	0.2 g
Water	1000 ml

*Obtained from Böhme Fettchemie, GmbH, Düsseldorf, Germany.

OTHER ISOLATION MEDIA FOR *AEROMONAS*

Other media that have been mentioned as being useful for the isolation of *Aeromonas* include: alkaline peptone water (Millership and Chattopadhyay, 1984), xylose-deoxycholate-citrate agar (Millership and Chattopadhyay, 1984), bile salts-brilliant green agar (Millership and Chattopadhyay, 1984), and starch-ampicillin agar (Palumbo et al., 1985).

Use of Selective Media

We feel that selective media have a limited role in the routine clinical microbiology laboratory, but can be used in laboratories specifically evaluating the role of *Aeromonas* in diarrhea or isolating *Aeromonas* from the environment. There is no universal agreement that a single *Aeromonas* medium is superior to the others for a given application.

Identification of *Aeromonas*

Strains of *Aeromonas* are small Gram-negative rods that have no outstanding morphological features. They usually have a single polar flagellum (Fig. 1), but flagellar strains are not normally used in identification. The *A. salmonicida* and *A. hydrophila* groups are very different in their phenotypic characteristics. *A. salmonicida* is likely to

Fig. 1. Cellular morphology of *A. hydrophila*. (A) is redrawn from a photomicrograph of a flagella stain given in Fig. 1 of Ewing et al. (1961). With flagellar stains, the flagella appear much larger than actual size. (B), (C), and (D) are redrawn from some electron micrographs in Plate 1 of Eddy (1960). Bars = 1 μ m.

Table 3. Differentiation and properties of the species groups and species of the *Aeromonas hydrophila* group that occur in human clinical specimens.

Test or property	DNA hybridization group ^a			Species ^b

Symbols: +, most strains are positive; (+), many strains are positive; –, most strains are negative; V, variable and of limited value in differentiation.

^a*A. hydrophila*, *A. caviae*, and *A. sobria* are each composed of two or more DNA hybridization groups. The data for these three species were adapted from Janda et al. (1983), Popoff (1984), and Sakazaki and Balows (1981). The media, incubation times, and temperatures vary from author to author.

^bThe data for *A. veronii* and *A. schubertii* are based on stains studied in our own laboratory (36°C, 2 days incubation).

be isolated only by those who work with fish diseases.

Strains of the *A. hydrophila* group grow both in the presence and absence of oxygen, ferment glucose (sometimes with gas production), are oxidase- and catalase-positive, grow well on most enteric plating media, do not require Na⁺ for growth, are not inhibited by the vibriostatic compound 0129, and are usually resistant to penicillins. The test results useful for identification and differentiation are given in Table 3. Some of the tests results are dependent on media and temperature.

There is considerable variability in the biochemical reactions of the motile *Aeromonas* species (Ewing et al., 1961; Janda, 1985). Some strains with unusual reactions, such as those that are mannitol negative or ornithine decarboxylase-positive, were eventually recognized as new species, but other atypical strains of *Aeromonas* have been described (Hansen and Glupczynski, 1984) and may represent new species or new biogroups of existing species. Some strains of

Aeromonas ferment lactose rapidly at 37°C, and Leclerc and Buttiaux (1962) found that this was an important source of error (30% of 9,036 samples) in counts of coliform bacteria in drinking water. Occasionally, strains of the *A. hydrophila* group produce brown pigment (Ross, 1962), a property usually associated with *A. salmonicida*.

Oxidase Test

McGrath et al. (1977) found that an isolate from bile was oxidase-positive (Kovacs method with tetramethylphenylenediamine dihydrochloride) when it was grown on five different nonselective media, but was oxidase-negative when grown on XLD agar, EMB agar, SS agar, or brilliant green agar. The next six strains of *Aeromonas* isolated in the laboratory were oxidase positive on all media tested. In a subsequent study, it was found that eight of 100 strains of *Aeromonas* had this medium-dependent reaction, and all eight were lactose fermenters on enteric isolation media (Overman et al., 1979). Other lactose-positive

strains of *Aeromonas* did not have this medium-dependent oxidase reaction, nor did any of the lactose-negative strains.

Decarboxylase Reactions

Since the decarboxylase reactions are important in the identification of *Aeromonas*, Altwegg et al. (1987) compared five different media for the determination of lysine and ornithine decarboxylase and arginine dihydrolase. There was considerable variation in the five media and also variation depending on the temperature of incubation and time at which the reactions was read.

Identification in the Clinical Microbiology Laboratory

Hemolytic colonies of “enteric”-type organisms on sheep blood agar should be considered as being suspicious for *Aeromonas*. Oxidase testing quickly rules out hemolytic strains of Enterobacteriaceae, but does not rule out *Vibrio cholerae* non-O1, which is another hemolytic oxidase-positive species that can occur in clinical specimens. Biochemical testing is required to complete the identification, and to differentiate some of the species in the *A. hydrophila* group (Table 3). This testing can be done in conventional tubed media or in commercial identification systems. Commercial systems are usually good in identifying a strain as belonging to the *A. hydrophila* group but they vary in ability or attempts to split this broad group. Some systems report the three main subgroups *A. hydrophila*, *A. sobria*, and *A. caviae*; others report *A. hydrophila* (in a broad sense, meaning the whole group); the *A. hydrophila* group; or simply *Aeromonas*. Several of the commercial identification systems that include *Aeromonas* have been evaluated by a number of

authors (Altwegg and Zollinger-Iten, 1987; Greene et al., 1984; Overman et al., 1979; Teska et al., 1989; Toranzo et al., 1986).

Strains of the *A. hydrophila* group can be confused with *V. cholerae*, *V. fluvialis*, and *V. furnissii*. However these organisms are quite distinct, as can be shown with complete testing (Table 4). Strains of *Aeromonas* grow in nutrient broth with no added NaCl, which is in contrast to most species of *Vibrio* which require Na⁺. *A. veronii* has the same decarboxylase pattern as *V. cholerae* (lysine-positive, arginine-negative, ornithine-positive), but these two species can be differentiated with complete biochemical testing or antibiotic susceptibility testing (Table 4).

Screening Tests

In large environmental surveys it is often desirable to screen colonies and discard those not likely to be *Aeromonas*. Kaper et al. (1979) suggested the use of “AH medium” as a simple way to identify *Aeromonas* cultures, which reacted differently from many other common organisms (Table 5). Interestingly, Toranzo et al. (1986) found that the result for several of the tests in this screening medium did not agree with the results when the test was done in a standard tube test.

AH Medium

Proteose peptone	5 g
Yeast extract	3 g
Tryptone	10 g
L-Ornithine hydrochloride	5 g
D-Mannitol	1 g
myo-Inositol	10 g
Sodium thiosulfate	0.4 g
Ferric ammonium citrate	0.5 g
Bromocresol purple	0.02 g
Agar	3 g
Water	1 liter

Table 4. Differentiation of the arginine positive species of *Vibrio* (*V. damsela*, *V. fluvialis*, and *V. furnissii*) and comparison with *Aeromonas*.

Test or property	<i>V. damsela</i>	<i>V. fluvialis</i>	<i>V. furnissii</i>	<i>Aeromonas</i>
Growth in nutrient broth with:				
No added NaCl	—	—	—	+
1% NaCl	+	+	+	+
Voges-Proskauer	+	—	—	V
Simmons citrate	—	+	+	V
Fermentation of:				
D-Galacturonic acid	—	+	+	—
L-Arabinose	—	+	+	V
D-Mannitol	—	+	+	+
Sucrose	—	+	+	(+)
Gas production during fermentation	V	—	+	V

<i>Proteus</i> sp.	Red	K or A	+	V	V
<i>Yersinia enterocolitica</i>	K or N	K or N	—	—	V
<i>Citrobacter</i> sp.	K	A or K	+	+	—
<i>Serratia</i> sp.	N or K	N or K	+	—	—

Symbols: K, alkaline reaction; A, acid reaction; N, a bleached neutral color due to decolorization of the indicator; +, 90% or more are positive; —, 10% or less are positive; V, strain to strain variation (11–89% positive).

Suspend the ingredients in the water. Adjust to pH 6.7, and heat to boiling to dissolve the agar. Dispense 5 ml into 13 by 100 mm screw-cap tubes and autoclave at 121°C for 12 min. Cool and store in the refrigerator.

With a straight wire, pick colonies that are suspicious for *Aeromonas*, and stab into the medium going all the way to the bottom of the tube.

Other Screening Tests

Other useful tests that can be used for *Aeromonas* screening include: ampicillin resistance, starch or dextrin fermentation, and a positive reaction for DNase and Tween-80 hydrolysis. As previously mentioned, these reactions are often incorporated in selective-differential media for *Aeromonas*.

Serotyping

Until recently there was no complete antigenic schema for serotyping *Aeromonas*. Ewing et al. (1961) established a preliminary serotyping system for *Aeromonas* by defining 12 somatic (O) and 9 flagellar (H) antigens. For many years there was little interest in further developing the schema. However, Sakazaki and Shimada (1984) described a schema with 44 O antigens that was useful for typing all the species included in the *A. hydrophila* group. The schema was based on antisera produced in rabbits with O antigen preparations (heated cultures). Unfortunately, most of the sera contained “rough-agglutinins” and required absorption with strain 1281–87 (a rough strain) before they could be used in routine typing. Some of the O antigens of *Aeromonas* were similar or identical to O antigens of *V. cholerae* or *Plesiomonas shigelloides*. This schema and its subsequent refinements should be useful in epidemiological and ecological studies and may help to define the etiological role of *Aeromonas* in diarrhea. Several other typing methods have been used to differentiate strains

below the level of species, but these are more specialized or difficult to do routinely.

Antibiotic Susceptibility

Most strains of *Aeromonas* are susceptible to the antibiotics chloramphenicol, tetracycline, trimethoprim-sulfamethoxazole, gentamicin, amikacin, nitrofurantoin, tobramycin, and third-generation cephalosporins. Most strains are resistant to penicillin, ampicillin, carbenicillin, methicillin, erythromycin, clindamycin, and vancomycin. About 50% of the strains are also resistant to piperacillin, mezlocillin, and second-generation cephalosporins (cefoxitin and cephmandole) (Motyl et al., 1985). The susceptibility patterns of *A. hydrophila*, *A. sobria*, and *A. caviae* are very similar. Some strains of *A. caviae* apparently do not produce β -lactamases and are sensitive to ampicillin (Richardson et al., 1982). Strains with transferable antibiotic resistance have been described, particularly in developing countries, but they are relatively rare in human clinical specimens. R factor-containing strains can also be important in the fish farming industry because antibiotic usage is a strong selective pressure for the development of resistance (Popoff and Devaine, 1971).

Identification of *Aeromonas salmonicida* (Sakazaki and Balows, 1981)

Strains isolated from diseased fish are probably *A. salmonicida*, if they are Gram-negative, fermentative, rod-shaped, nonmotile, oxidase-positive, grow at 25°C but not at 36°C, and produce a soluble brown pigment. The identification can be confirmed with a complete set of biochemical reactions and perhaps other testing. Strains of *A. salmonicida* usually produce extracellular enzymes such as gelatinase, amylase, lecithinase, and lipase. They ferment D-glucose, usually with slight gas production, and most strains ferment

Table 6. Differentiation of the three subgroups (subspecies) of *Aeromonas salmonicida*.

	Subgroup		
	salmonicida	achromogenes	masoucida
Brown soluble pigment	+	–	–

14	–	+	+	–	–	–	–	–	2

Adapted from Popoff and Vieu (1970) and Popoff and Lallier (1984).

L-arabinose, D-galactose, D-mannose, and D-mannitol. Many strains produce indole. Three subgroups of *A. salmonicida* have been defined based on phenotypic properties (Table 6), and these are sometimes considered as subspecies. A phage typing scheme (Table 7) which may have application in epidemiological studies, has been described by Popoff and Vieu (1970).

Graevenitz, 1980). *P. shigelloides* causes extraintestinal infections of humans and animals, and is occasionally isolated from human feces where at least some strains may cause diarrhea, particularly in the tropics. There is some information on the basic biology of *P. shigelloides*, but it has not been a particularly popular organism for this type of work.

The Genus *Plesiomonas*

Plesiomonas is a relatively new genus in the family Vibrionaceae. Since it was first described in 1948, there have been over 250 papers that at least mention it, and several good reviews are available (Brenden et al., 1988; Eddy and Carpenter, 1964; Holmberg and Farmer, 1984; International Workshop, 1986, 1988, 1990; Miller and Koburger, 1985; Sakazaki et al., 1959; Sakazaki and Balows, 1981; Schubert, 1981, 1984; von

History, Nomenclature, and Classification of *Plesiomonas*

The organism that is now known as *P. shigelloides* was first described by Ferguson and Henderson (1947), who isolated an organism on MacConkey agar from a fecal specimen and called it “strain C27.” They studied the culture with the biochemical and serological methods generally available in 1947 and concluded that strain C27 was “a motile strain of the family

Enterobacteriaceae containing a somatic antigen similar to the major antigen of *Shigella sonnei* phase I..." It was thought to be a member of the "paracolon group" of Enterobacteriaceae.

The classification of Ferguson's C27 group was confusing for many years, and it was classified in a number of different genera and species. Bader (1954) studied a strain of the C27 group and determined that it had a tuft of flagella at one pole similar to the polar flagella of *Pseudomonas*, and proposed the name *Pseudomonas shigelloides*. This was the first proposal of a scientific name, and the species name "shigelloides" has been used for this organism regardless of the genus in which it is classified. Other investigators isolated strains similar to strain C27 and noted the similarity to some of the species in the family Enterobacteriaceae (Cowan, 1956). Cowan (1956) proposed classifying the C27 strains along with *Shigella sonnei* in the genus *Escherichia*. Ewing et al. (1961) studied strains of the C27 group along with a large collection of *Aeromonas* strains and noted that the strains fermented rather than oxidized glucose, and proposed that *Pseudomonas shigelloides* be reclassified in the genus *Aeromonas* as *Aeromonas shigelloides*. Habs and Schubert (1962) studied strains of *Aeromonas shigelloides*, along with strains of *Aeromonas* and other Vibrionaceae, and concluded that *Aeromonas shigelloides* should be removed from the genus *Aeromonas* and classified in a new genus which they named *Plesiomonas*. This proposal agreed with the GC content of the DNA of *Plesiomonas* (51 mol%) compared to *Aeromonas* (57–60 mol%) and *Vibrio* (40–50 mol%). Thus, in 1962, the C27 organism was renamed *Plesiomonas shigelloides*, and Habs and Schubert's classification has become universally accepted with time.

Classification Based on Nucleic Acid Hybridization and Sequencing

Several studies have used molecular techniques to compare strains of *P. shigelloides* with other species of the Enterobacteriaceae or Vibrionaceae. Fanning et al. (1985) found that strains of *P. shigelloides* were highly related to each other by DNA-DNA hybridization and that *P. shigelloides* was a well defined species based on this criterion. The type strain of *P. shigelloides* was only 8% related by DNA hybridization to *Escherichia coli*, 7% related to the type strain of *Vibrio cholerae* and the 8% related to the type strain of *Aeromonas hydrophila*. *P. shigelloides* was not closely related to any of the other species of Enterobacteriaceae or Vibrionaceae tested. Although *Plesiomonas* has been classified in a number of other genera over the years, including *Aeromonas* (Ewing et al., 1961), *Scatomonas*,

Fergusonia (Sebald and Veron, 1963), and *Vibrio* (Hendrie et al., 1971), most authors use the genus name *Plesiomonas* with a single species *P. shigelloides*. However, as described in The Family Vibrionaceae in this Volume, there is a difference of opinion on whether *Plesiomonas* should be classified in the family Enterobacteriaceae or Vibrionaceae. Table 4 in The Family Vibrionaceae in this Volume indicates that *Plesiomonas* has some characteristics in common with both of these families.

MacDonell and Colwell (1985) recently compared the 5S rRNA sequences of a number of Enterobacteriaceae and Vibrionaceae, and concluded that *P. shigelloides* was more closely related to *Proteus mirabilis* and *P. vulgaris* than to any of the species of Vibrionaceae tested. They concluded that *Plesimonas* should be moved to the family Enterobacteriaceae and be included in the genus *Proteus* as *Proteus shigelloides*. The 5S rRNA sequence data of MacDonell and Colwell (1985) also indicated that *Vibrio cholerae* and *V. mimicus* are not closely related, a conclusion difficult to reconcile with the known similarity of these two species, both phenotypically and genetically. This discrepancy must be considered in the evaluation of their proposal.

Origin of the Name *Plesiomonas*

Plesiomonas is derived from the Greek masculine noun "plesios," which means neighbor (to *Aeromonas*), and from the Greek feminine noun "monas" which means "monad" or "unit" (Schubert, 1984). Thus, a literal meaning would be "the neighbor monad," or less literally, "the organism that is neighbor to, or has traditionally been associated with *Aeromonas*." The type species for the genus *Plesiomonas* is *P. shigelloides*, and ATCC 14029 (= NCIB 9242) is the type strain. Many of the scientists that currently study the organism pronounce it *Ple-si-o-mo;pr-nas* (Plee-see-oh-moh;pr-nas), but others pronounce it *Ples;pr-i-o-mo-nas* (Pless;pr-ee-oh-moh-nas). Schubert (Schubert, 1984) gives the former as the pronunciation, which follows the recommendation that has always been given in *Bergey's Manual of Determinative Bacteriology*. The species name "shigelloides" is a modern Latin feminine noun meaning "similar to *Shigella*," or "*Shigella*-like." The species was given this name because many of the original strains agglutinated in *Shigella sonnei* antiserum and were somewhat inactive biochemically like *Shigella*.

Morphology and Metabolism of *Plesiomonas*

P. shigelloides is a small Gram-negative rod measuring 2–3 µm long by 0.7 to 0.8 µm wide (Ewing

Fig. 2. Cellular morphology of *P. shigelloides*; (A) to (F) are redrawn from photomicrographs of flagellar stains given in Fig. 1 of Ewing et al. (1961); note that both polar and lateral flagella are visible. With flagellar stains, the flagella appear much larger than actual size. Bars = 1 μ m.

et al., 1961). Most strains are motile and flagellar strains or electron micrographs (Fig. 2) show two to seven flagella located at one end of the cell. Young cultures may also produce lateral flagella with a shorter wave length (Sakazaki and Balows, 1981). There is disagreement among different authors on the length and wave length of the flagella produced (Ewing et al., 1961; Schubert, 1984). Strains of *P. shigelloides* have few other outstanding structural features. Distinct capsules are not produced, but most strains apparently produce a heat-labile capsular substance that blocks agglutination of living cells with homologous O antisera (Shimada and Sakazaki, 1978; 1985). Schubert (1984) stated that *P. shigelloides* does not produce granules, but metachromatic granules that stain with methylene blue have been reported in two studies (Brenden et al., 1988; Pastian, 1984). Brenden et al. (1988) did electron microscopy and showed that structures resembling granules are produced. Their electron micrographs (ruthenium-red staining) also showed a glycocalyx surrounding the cell, which could be the substance that blocks O agglutination. The cellular fatty acid content of *P. shigelloides* strains is similar to that of other species of Enterobacteriaceae and Vibrionaceae (Lambert et al., 1983). Unlike other species of Vibrionaceae, *P. shigelloides* contains the enterobacterial common antigen (Kaluzewski and Czech, 1976; Whang et al., 1972). It also produces lipid A (Basu et al., 1985).

There have been a few studies on the metabolism, physiology, and genetics of *Plesiomonas*. The GC content of DNA is 51 mol% (Sebald and Véron, 1963). Herrington et al. (1987) found that all five strains of *P. shigelloides* contained a single large plasmid that may be important as the genetic determinant of a virulence factor in infections of the intestinal tract. Olsvik et al. (1985) found several different plasmid patterns in a small group of *P. shigelloides* strains isolated

in Peru, and concluded that there was no evidence that *P. shigelloides* produced a plasmid similar to or identical with the *Shigella* invasiveness plasmid. Unlike *Aeromonas*, strains of *P. shigelloides* do not grow at 0–5°C, and only a few strains grow at 8°C (Miller et al., 1986b; Schubert, 1984). The optimum growth temperature for *P. shigelloides* appears to be 38–39°C, with a maximum growth temperature of 40–44°C. About 25% of strains grow at 45°C (Miller et al., 1986b; Schubert, 1984). Strains of *P. shigelloides* may be particularly susceptible to drying. Sakazaki and Balows (1981) reported that unsealed stock cultures in tubes may die after a few days. Strains of *P. shigelloides* grow at pH 5–8 (Schubert, 1984) and may be particularly susceptible to low pH. Janda (1987) found that strains are rapidly killed at a pH below 4 and are also inhibited by substances produced by other intestinal bacteria, such as *Streptococcus faecium* and *Pseudomonas aeruginosa*. These factors may be important in the survival and multiplication of *P. shigelloides* in the human intestinal tract.

Habitats of *Plesiomonas*

P. shigelloides has been isolated from human feces, extraintestinal specimens, animals, and the environment, particularly water (Sakazaki and Balows, 1981; Schubert, 1984), and most strains have been isolated during warm weather. Unlike *Aeromonas*, *P. shigelloides* does not grow at 0–5°C, which may hinder its survival in the environment during the cold months. *P. shigelloides* has been isolated in many different countries.

Human Extraintestinal Infections

P. shigelloides is rarely isolated in most clinical microbiology laboratories but it can occur in a variety of clinical specimens including CSF

(Appelbaum et al., 1978; Dudley et al., 1982; Horst et al., 1982; Su and Choo, 1981), blood (Ellner and McCarthy, 1973; Pathak et al., 1983), wounds, and the respiratory tract. It has also been isolated from cases of cholecystitis, proctitis (Nolte et al., 1988), septic arthritis (Gordon et al., 1983), and endophthalmitis (Cohen et al., 1983). Many literature reports describe cases of meningitis and bacteremia, but this may reflect greater interest in reporting these cases due to their seriousness. *P. shigelloides* causes localized infections after trauma and spontaneous inoculation into the wound of bacteria from an environmental source such as water. A different mechanism involves a gastrointestinal origin from which it is disseminated to other parts of the body. Most patients with serious extraintestinal infections have an underlying disease.

Human Intestinal Infections

The first reported isolate of *P. shigelloides* (Ferguson and Henderson, 1947) and most subsequent isolates have been from feces. There is a consensus that *P. shigelloides* may be an enteric pathogen in adults and children (McNeeley et al., 1984). A few fatal cases have been reported (Sawle et al., 1986).

However, there is considerable confusion in the literature on the actual etiological role of *P. shigelloides* in particular cases and studies. Many authors have overstated the evidence that *P. shigelloides* actually caused the infection(s). Based on extensive literature reports, we feel it is safe to conclude that "some strain of *P. shigelloides* probably cause diarrhea in at least some people." This would be analogous to the situation with *Escherichia coli* and *Yersinia enterocolitica*, where only certain strains are able to cause diarrhea. The role of the host is also likely to be important.

HUMANS WITHOUT DIARRHEA In industrialized countries, *P. shigelloides* is rarely found in the feces of healthy people. The largest culture survey was done in Japan by Arai et al. (1980) who found only 3 carriers among 38,454 (0.0078%) food handlers and school children. A higher carriage rate was found by Pauckova and Fukava (1968). They studied hospitalized patients without diarrhea in Czechoslovakia and found that 15 of 10,643 (0.14%) were positive. In developing countries, the situation is quite different. In Thailand, Pitarangsi et al. (1982) found that 12 of 51 (24%) adults were colonized.

ANTIBODY RESPONSE AND SERODIAGNOSIS The results of serological testing for *P. shigelloides* in patients with diarrhea have generally been negative, and these data are viewed as negative

evidence for the etiological role of most *P. shigelloides* strains in diarrhea. Only a few authors have tested stool isolates of *P. shigelloides* with serum to detect antibodies to O or H antigens. Most control sera (patients with no documented exposure to *P. shigelloides*) have no titer or a very low titer (Claesson et al., 1984; Holmberg et al., 1986).

EPIDEMIOLOGY *P. shigelloides* is rarely isolated in industrialized countries, but it is frequently found in developing countries with tropical and subtropical climates. Most reports have been about sporadic cases, but a few outbreaks have been reported (Ueda et al., 1963). In developing countries, most diarrhea cases have been exposed to water, animals, or environmental water. Most diarrhea cases that have been positive for *P. shigelloides* have occurred during the summer, which correlates with the frequent presence of the organism in water and the environment during warm weather. In developing tropical countries, drinking water from streams, lakes, and wells is often contaminated with *P. shigelloides* (Bhat et al., 1974; Sanyal et al., 1980; Tsukamoto et al., 1978). *P. shigelloides* strains in water reservoirs can survive purification and occur in tap water.

In industrialized countries, different factors seem to be important in the acquisition of *P. shigelloides*. These include travel to developing countries (Herrington et al., 1987; Holmberg et al., 1986) and eating raw shellfish (Holmberg et al., 1986).

Animals implicated as sources for *P. shigelloides* include oysters (Holmberg et al., 1986; Ratula et al., 1982), fish (Hori et al., 1966), shrimp (Holmberg et al., 1986), and chickens (Newsom and Gallois, 1982).

TREATMENT Symptoms in diarrhea patients with feces positive for *P. shigelloides* usually resolve within a few days without specific treatment. Replacement of fluid and electrolytes is important if dehydration is severe (Rolston and Hopfer, 1984). Antibiotic treatment has generally been limited to those with chronic diarrhea or a serious underlying illness. Tetracycline (Reinhardt and George 1985; Rolston and Hopfer, 1984) and trimethoprim-sulfa (Rolston and Hopfer, 1984) usually result in eradication of the organism from the feces and resolution of symptoms. However, it must be emphasized that the etiological role of *P. shigelloides* in most of these reports is uncertain.

Pathogenesis of Intestinal Infections

Strains of *P. shigelloides* have been isolated from human cases with two different syndromes:

watery diarrhea, suggesting an enterotoxin; and diarrhea with blood and mucus, suggesting an invasive process. There is confusion in the literature whether *P. shigelloides* produces positive results in animal and other models designed to measure or correlate with these two processes. Most authors have studied strains isolated in their particular geographical area, and there have been no comparative studies in different laboratories with the same set of strains.

HUMAN VOLUNTEER STUDIES Herrington et al. (1987) fed *P. shigelloides* strain P012 to 33 human volunteers. This strain had been studied by Holmberg et al. (1986) and was from a 4-year-old diarrhea patient whose stool had blood, mucus, and white blood cells; the illness was acquired during foreign travel. None of the volunteers got diarrhea even though some received over 10^9 organisms and were given ampicillin to reduce normal intestinal flora. Gut colonization was slight, only 36% even shed the organism for a few days. None of the volunteers had a rise in antibody titer (hemagglutination). These results agreed with the unpublished studies done in Japan (Sakazaki et al., 1959; Sakazaki and Balows, 1981) where a strain of *P. shigelloides* with the 0 antigen of *Shigella sonnei* did not produce diarrhea in human-feeding experiments.

GERM-FREE PIGLETS Herrington et al. (1987) obtained some positive results when *P. shigelloides* strains P012 was fed to germ-free piglets. This strain caused mild to moderate diarrhea in 3 of 3 piglets when 10^9 cells were given. There was pathology in both the small and large intestine. The organism colonized the small intestine and appeared to penetrate epithelial enterocytes, and could be seen inside vacuoles. Large numbers of organisms were found in the jejunum (10^5) and in the distal small intestine (10^8). In the large intestine, there was inflammation, mucosal edema, and some disruptions of epithelia. Strain P012 contained a large plasmid which is apparently important, because there were no symptoms or cell penetration when a strain cured of the plasmid was used in the piglet model.

MONKEYS Pitarangsi et al. (1982) found negative results when one strain was fed to five Rhesus monkeys, but commented that this might not be a good model since monkeys are often colonized with *P. shigelloides* and may have immunity.

ADULT RABBITS Herrington et al. (1987) obtained negative results when their plasmid-containing strain (see above) and several other strains were fed to adult rabbits (intestinal tie, adult rabbit model).

RABBIT ILEAL LOOPS There is confusion about whether *P. shigelloides* is positive or negative in the rabbit ileal loop model. Sanyal et al. (1975) reported that all six of their strains were negative for fluid accumulation (live cells injected into intestinal loop segments), but the strains multiplied slightly. Pitarangsi et al. (1982) also found negative results for 27 strains isolated in Thailand. However, positive results have been reported in other studies. Sanyal et al. (1980) found that live cells of 13 strains isolated in India multiplied by 10^4 and caused fluid accumulation. Interestingly, several strains required loop-to-loop passage before a positive reaction was obtained. When heated supernatants were injected into loops, there was as much fluid accumulation as when live cells were used. They concluded that a "heat-stable toxin" was responsible for fluid accumulation. Positive results in this model were obtained with live cells by Huq and Islam (1983) and with filtrates by Manorama et al. (1983). The latter authors purified material from the culture filtrates, and concluded that both a heat-labile and a heat-stable enterotoxin might be involved.

INFANT MOUSE ASSAY The results in the infant mouse assay are similar to those found with the rabbit ileal loop assay. Several authors found their strains to be uniformly negative (Johnson and Lior, 1981; Pitarangsi et al., 1982), but others obtained positive results (Huq and Islam, 1983; Manorama et al., 1983; Sanyal et al., 1980). Manorama et al. (1983) felt that both a heat-stable and a heat-labile enterotoxin was responsible for fluid accumulation in the infant mouse model, a result similar their results in the rabbit ileal loop.

TISSUE CULTURE ASSAYS FOR ENTEROTOXINS Several tissue culture cell lines that traditionally have been used to measure *E. coli* enterotoxins and cholera toxin have been used to test filtrates of *P. shigelloides*. Several authors reported positive results with Y1 cells (mouse adrenal tumor cells) (Gurwith and Williams, 1977; Ljungh et al., 1977; Sanyal et al., 1980) but others reported uniformly negative results (Johnson and Lior, 1981; Pitarangsi et al., 1982). Both Gardner et al. (1987) and Sanyal et al. (1975) obtained positive results for CHO (Chinese hamster ovary) cells, but Johnson and Lior (1981) obtained negative results with a different group of strains. Binns et al. (1984) found some cytopathic effects against HeLa cells. Holmberg et al. (1986) found that their strains isolated in the United States were negative for Shiga-like toxins.

INVASION OF HeLa CELLS Binns et al. (1984) found that 3 of 16 strains of *P. shigelloides* were strongly invasive in a manner similar to *Shigella*

strain. Similarly, Olsvik et al. (1985) found that some of their strains isolated in Peru were positive. These results contrast to those of Herrington et al. (1987) who found that all five strains isolated in the United States were negative.

GUINEA PIG EYE (SERENY TEST) This model is used to show invasiveness for *E. coli*, *Shigella*, and *Yersinia*. All strains of *P. shigelloides* tested have been negative (Binns et al., 1984; Herrington et al., 1987; Holmberg et al., 1986; Johnson and Lior, 1981; Pitarangsi et al., 1982; Sanyal et al., 1975). In addition, none of the five strains studied by Herrington et al. (1987) reacted with a DNA probe made from the *E. coli-Shigella* invasiveness genes.

RELATIONSHIPS TO *E. COLI* ENTEROTOXINS Although few if any strains from the far east have been tested, strains of *P. shigelloides* have been negative when tested in an ELISA assay for *E. coli* heat-labile enterotoxin (Herrington et al., 1987) or by a DNA probe assay for *E. coli* heat-stable toxin (Herrington et al., 1987; Holmberg et al., 1986).

The Role of *P. shigelloides* in Diarrhea

It is difficult to reconcile some of the conflicting literature reports, but several factors seem important. Different strains have been used by different investigators, so no direct comparisons of results have been made. Most of the studies done in industrialized countries have used strains isolated locally rather than strains isolated in developing countries, which could minimize the likelihood of obtaining pathogenic strains. Different media and growth conditions have been used, which could drastically affect the production of virulence factors, toxins, and other biologically active molecules. Evidence from one study (Sanyal et al., 1980) suggests that strains negative for pathogenicity can become positive after animal passage. This finding, along with the possible role of a virulence plasmid (Herrington et al., 1987), suggests that unstable virulence factors may be involved. For these reasons it seems very desirable to use freshly isolated strains that have not been maintained on laboratory media. In summary, there is some evidence from animal and other virulence models for both enterotoxins and for invasiveness, however, there are no virulence factors that are widely accepted as being important or that should be tested for routinely.

Animals and *Plesiomonas*

P. shigelloides has been isolated from a wide variety of animals, including dogs (Arai et al., 1980), cats (Aldová, 1985; Arai et al., 1980), rats

(Aldová et al., 1980), zoo animals (Bauwens et al., 1983), monkeys (Pitarangsi et al., 1982), chimpanzees (Sakazaki et al., 1959), cattle, pigs (Aldová et al., 1980), poultry, rodents, and shrews (Chenchittikul et al., 1983), vultures (Winsor et al., 1981), turtles (Sugita and Deguchi, 1983), snakes (Davis et al., 1978), fish (Arai et al., 1980; Van Damme and Vandepitte, 1980; Miller and Koburger, 1986a), frogs (Sugita et al., 1985), newts (Arai et al., 1980; Tsukamoto et al., 1978), and shellfish (Arai et al., 1980). The occurrence of *P. shigelloides* in most of these animals is probably related to its frequent occurrence in environmental water.

ANIMAL DISEASES Animal diseases due to *P. shigelloides* have rarely been reported. Walsh et al. (1987) reported an infection of the umbilical area (ophthalitis) and peritonitis in a manatee in Florida. Cruz et al. (1986) reported that *P. shigelloides* causes septicemia in rainbow trout.

Water

P. shigelloides has been isolated frequently from fresh water such as rivers and streams (Arai et al., 1980; Sanyal et al., 1975; Schubert, 1981; Tsukamoto et al., 1978), lakes and ponds (Tsukamoto et al., 1978; Van Damme and Vandepitte, 1980), estuaries, and aquaria for tropical fish (Sanyal et al., 1987). There is considerable variation in the number of organism present ranging from 10,000 per 100 ml in a Florida estuary to 10 per 100 ml in the river Main in Germany. It appears that *P. shigelloides* does not actually multiply in the water column but may multiply in sediments (Sanyal et al., 1975; Tsukamoto et al., 1978) or in the guts of aquatic animals, who then defecate into the water. Arai et al. (1980) isolated *P. shigelloides* from rivers in Japan, but only in the warmer months (July through November). *P. shigelloides* has also been isolated from well water (Bhat et al., 1974), water treatment plants (Sanyal et al., 1980), and tap water (Tsukamoto et al., 1978). These sources indicate that people can easily be exposed to *P. shigelloides* through drinking water. The organism is probably much more common in the tropics because of the warmer temperatures, and is found more frequently in human feces there because people tend to drink well and surface water. *P. shigelloides* has also been isolated from seawater (Sakazaki and Balows, 1981; Zakhariev, 1971), but it appears to be a transient organism.

Isolation of *Plesiomonas*

Most laboratories do not use special media or methods to isolate *P. shigelloides*. Thus, if this

species is greatly outnumbered by other organisms it will probably be missed. This led to the development and evaluation of special media and methods.

Normal Plating Media

P. shigelloides grows well on most plating media used in enteric bacteriology and forms colonies 1–2 mm in diameter after 24 hours of incubation. On nutrient agar *P. shigelloides* forms moist smooth colonies (colony type 1), but many strains contain up to four other colony types (Sakazaki et al., 1959). Colony type 1 was considered to be the parent colony type, which dissociated into the other types. On blood agar *P. shigelloides* forms smooth colonies without hemolysis, although a few hemolytic strains have been reported (Aldová et al., 1966; Zajc-Satler et al., 1972). Most strains of *P. shigelloides* are colorless or pink on MacConkey agar, but a few strains ferment lactose rapidly and are red. Old stock cultures of these strong-lactose-fermenting strains will usually have white, pink, and red colonies on MacConkey agar, and thus appear to be a mixed culture. Strains of *P. shigelloides* also grow on deoxycholate agar and Hektoen agar, and usually appear as nonlactose fermenters. In a study of *P. shigelloides* from fresh fish in Zaire, Van Damme and Vandepitte (1980) found that MacConkey agar was a better plating medium than XLD or SS agar for plating subcultures from tetrathionate broth enrichments.

Special Media for *Plesiomonas*

Several media and methods have been designed to selectively isolate *P. shigelloides*. Although *P. shigelloides* is moderately resistant to ampicillin, the ampicillin-containing selective media designed for the isolation of *Aeromonas* are too inhibitory and have not proved useful in isolation. Brilliant green has been used in several broths and agars. Strains of *P. shigelloides* grow in the presence of 0.0005 g/l brilliant green (Millership and Chattopadhyay, 1984; Schubert, 1977) per l but 0.01 g/l is inhibitory (Millership and Chattopadhyay, 1984). Strains of *P. shigelloides* are also resistant to bile salts, which are usually incorporated in media to inhibit Gram-positive bacteria. Most bacterial species do not ferment myo-inositol, but almost all strains of *P. shigelloides* ferment this naturally occurring cyclic polyhydroxyl alcohol. Schubert (1977) took advantage of the three properties discussed above, and designed inositol-brilliant green-bile salts agar.

Inositol-Brilliant Green-Bile Salts Agar (*Plesimonas* Differential Agar)

The following formula is the one given by given by E. Merck, Germany, which at one time produced and sold this medium under the name “*Plesimonas* Differential Agar,” catalog no 15106.

Peptone	7.5 g
Meat extract	7.5 g
Sodium chloride	5 g
Bile salts mixture	8.5 g
Brilliant green	0.00033 g
Neutral red	0.025 g
Inositol	10 g
Agar	13.5 g
Water	1 liter

Agar pH 7.2. Suspend the ingredients in the water and heat to boiling to dissolve. Autoclave at 121°C for 15 min. Cool to 45°C and pour into petri dishes.

Inoculate the plates and incubate at 37°C for 48 h. Colonies of *P. shigelloides* ferment the inositol and appear red. Merck states that “whitish *P. shigelloides* colonies grow after incubating for a maximum of 48 hours; they display a reddish colouration the intensity of which depends on the distance separating them from neighboring colonies.”

Miller and Koburger (1986a) found that inositol-brilliant green-bile salts agar was more effective than *Plesiomonas* agar, and that strains grew poorly if they had been stressed by heat or cold. This suggests that a period of pre-enrichment in a nonselective broth may be desirable before the use of more inhibitory media. Huq and Akhter (International Workshop, 1988) compared modified Salmonella-Shigella agar, inositol-brilliant green-bile salts agar, and *Plesiomonas* differential agar, and found the best results with *Plesiomonas* differential agar incubated at 42°C for 24 h, rather than at 37°C for 48 h.

Identification of *Plesiomonas*

P. shigelloides is easy to identify with standard biochemical tests or commercial identification systems. *P. shigelloides* is oxidase positive, which differentiates it from species of Enterobacteriaceae with which it could otherwise be confused. Strains of *P. shigelloides* ferment myo-inositol; are positive for lysine decarboxylase, ornithine decarboxylase, and arginine dihydrolase; and do not require added sodium chloride for growth. This unique pattern differentiates it from other species of Vibrionaceae.

Biochemical Characteristics

Table 8 gives the biochemical characteristics of strains that were studied in our laboratory and compares the results with the 280 strains studied by Sakazaki and Balows (1981) and with the data from other reference laboratories (Holmes et al., 1986). Most of the positive biochemical reactions

Table 8. Biochemical reactions and other properties of *Plesiomonas shigelloides* as reported by different authors.

Test or property	Composite result ^b	Results obtained by:			
		Our laboratory; 70 strains ^c	Sakazaki and Balows (1981); 280 strains	Ewing et al. (1961); 50 strains	Holmes et al. (1986)

^aThe numbers give the percentage positive (after 48 h of incubation for our laboratory's results). Delayed reactions are given in parentheses (cumulative percentage positive at 7 days for our laboratory's data).

^bThese are arbitrary values based on examination of all data available; in most cases, they are weighted more heavily toward our results.

^cThirty-six strains were studied with a complete set of biochemical reactions; 34 were studied with fewer tests.

occurred at 24 hours, but some were delayed. For most tests, there is little strain-to-strain variation, which indicates there are few true biotypes of *P. shigelloides*. The variation in lactose fermentation is important because this sugar is an ingredient in many enteric plating media.

COMMERCIAL IDENTIFICATION SYSTEMS Several studies have indicated that the API 20E system accurately identifies *P. shigelloides* (Overman et al., 1985; Penn et al., 1982; Rolston and Hopfer, 1984; von Graevenitz and Bucher, 1983). The time of incubation could perhaps be reduced to 5 hours and still give a correct identification (Overman

and Overley, 1986). Other commercial systems have been studied less frequently, but several apparently give good results. These include the Enterotube (Holmes et al., 1977), Abbott Advantage—5 hr (Jorgensen et al., 1984), Pathotec system (Holmes et al., 1977), and Quantum II system (Sylvester and Washington, 1984). Most of the commercial identification systems have now include *P. shigelloides* in their data bases.

Serotyping

At least three different serotyping systems have been described for *Plesiomonas*. Sakazaki et al.

Table 9. The antigenic schema for *P. shigelloides* described by Shimada and Sakazaki.

Serotype (O and H antigen)	Number of strains	Serological cross-reactions

TOTAL	87	

Adapted from Sakazaki and Balows (1981).

(1959) studied Japanese strains and defined 50 O and 4 H antigens. Over the years, this schema has been expanded (Shimada and Sakazaki 1978), and now contains 50 O and 17 H antigens (Shimada and Sakazaki, 1985). Other serotyping schemas include those of Quincke (1967) with 16 O antigens, and Aldová and Geizer (1968) with 13 O and 5 H antigens, which has now been expanded to 30 O antigens (Aldová, 1985). Serotyping has not proved as useful as expected in defining the role of *P. shigelloides* in causing diarrhea, but it was used in several studies to show that human cases and water isolates had the same O and H antigens (Tsukamoto et al., 1978).

RELATIONSHIP TO *SHIGELLA SONNEI* *P. shigelloides* was originally discovered because it agglutinated in *Shigella sonnei* antiserum (Ferguson and Henderson, 1947). Other authors have noted this cross-reaction, but only about 25% of *P. shigelloides* strains have this serological relationship (Holmberg et al., 1986, Pitarangsi et al., 1982; Shimada and Sakazaki, 1985; Vandepitte et al., 1957). Only the strains of *P. shigelloides* that contain O antigen 17 (Table 9) agglutinate in the *S. sonnei* serum. Sack (International Workshop, 1988) speculated that the identity of the *Shigella sonnei* O antigen with *P. shigelloides* O antigen 17 may explain the rarity of *Shigella sonnei* in developing countries. In these countries, environmental exposure to *P. shigelloides* O 17 antigen would provide immunological protection against infection with *S. sonnei*. Because of better hygiene in industrialized countries, there would be less exposure to environmental strains of *P. shigelloides* and thus no protection against infection with *S. sonnei*.

Antibiotic Susceptibility

P. shigelloides is generally susceptible to antibiotics including many newly introduced ones (Dahm and Weinberg, 1980; Holmberg et al., 1986; Miller et al., 1983; O'Hare et al., 1985; Rolston and Hopfer, 1984), such as imipenem, ceftazidime, cefotiam, ceftriaxone, and cefotaxime (Brenden et al., 1988), and to the new quinolone antibiotics (O'Hare et al., 1985). Reports of antibiotic resistance have been rare. Holmberg et al. (1986) found occasional resistance to the sulfa drugs and to tetracycline. However, Olsvik et al. (1985) found that many of their strains isolated in Peru were resistant to gentamicin. There is some confusion in the literature about the resistance of *P. shigelloides* to ampicillin and other penicillin drugs.

- International Workshop. 1986. The First International Workshop on *Aeromonas* and *Plesiomonas* was held in Manchester England on 5–6 September 1986, as a satellite meeting of the XIV International Congress of Microbiology. One to three page summaries of the talks and posters sessions were published in an 87 page printed booklet. The journal *Experientia* (volume 43, pages 348–374, 1987) published summaries of 20 invited talks, but not the posters.
- International Workshop. 1988. The Second International Workshop on *Aeromonas* and *Plesiomonas* was held at the Eden Rock Hotel in Miami, Florida on 7 May 1988, in conjunction with the American Society for Microbiology's annual meeting. One to two page summaries of 13 talks and 1/2 page abstracts from the 39 posters were published in a 72 page printed booklet. (Copies were originally available and may still be from Dr. R. R. Colwell or Dr. S. W. Joseph, Department of Microbiology University of Maryland, College Park, Maryland 20742).
- International Workshop. 1990. The Third International Workshop on *Aeromonas* and *Plesiomonas* was held in LO-Skolen in Helsingör (Elsinore) Denmark on 5–6 September 1990. Details are available from Torkel Wadström and Åsa Ljungh, University of Lund, Department of Medical Microbiology, Sölvegatan 23, S-223 62 Lund, Sweden.

The Genus *Alteromonas* and Related Proteobacteria

VALERY V. MIKHAILOV, LYUDMILA A. ROMANENKO AND ELENA P. IVANOVA

Introduction

Many marine heterotrophic Gram-negative aerobic or facultatively anaerobic bacteria are affiliated to the genera *Alteromonas*, *Pseudoalteromonas*, *Glaciecola*, *Idiomarina* and *Colwellia*. They belong to the γ -subclass of the class *Proteobacteria* (Stackebrandt et al., 1988) and share similar phenotypic, genotypic and phylogenetic characteristics. These bacteria, essential components of the marine part of the biosphere, have very diverse habitats including coastal and open water areas, deep-sea and hydrothermal vents, and marine sediments. The genus *Alteromonas* was created by Baumann et al. (1972) for marine Gram-negative heterotrophic bacteria motile by a single polar flagellum, with an oxidative metabolism and a DNA G+C content of 38–50 mol%. On the basis of 16S rDNA gene sequence analysis, the genus *Alteromonas* was revised in 1995 to contain only one species, *A. macleodii*. The remaining species were reclassified as *Pseudoalteromonas* species (Gauthier et al., 1995). The genus *Glaciecola* was proposed by Bowman et al. (1998c) for two groups of psychrophilic, strictly aerobic chemoheterotrophic bacteria isolated from sea-ice diatom assemblages from coastal area of eastern Antarctica. Two deep-sea bacteria were isolated from seawater of the Pacific Ocean and described as species of the new genus *Idiomarina* (Ivanova et al., 2000b). Deming and coauthors accommodated facultatively anaerobic, psychrophilic and barophilic bacteria into the genus *Colwellia* (Deming et al., 1988). Recently a new genus, *Thalassomonas*, comprising marine pigmented bacteria that are phylogenetic neighbors of *Colwellia* was described by Macian et al. (2001).

History of the *Alteromonas* and *Pseudoalteromonas* Genera

Through 1994

In the 1950s, marine aerobic heterotrophic Gram-negative and nonfermentative *Pseudomonas*-like

bacteria with the low DNA G+C content of 40–50 mol% were assigned to the genus *Pseudomonas*, including *P. atlantica*, *P. carrageenovora* (Humm, 1946; Yaphe, 1955; Yaphe, 1957), *P. putrefaciens* (Lee et al., 1981) and *P. piscicida* (Bein, 1954; Buck et al., 1963). The numerical taxonomy and some identification schemes of marine *Pseudomonas*-like bacteria have been considered in a number of studies (Shewan et al., 1960; Gibson et al., 1977; Lee et al., 1977; Gray and Stuart, 1980; Oliver, 1982).

In 1972, Baumann and coauthors characterized 218 marine bacterial strains isolated from seawater samples collected in the area of the Hawaiian archipelago. Most of these bacteria were aerobic, Gram-negative and heterotrophic microorganisms, motile by a single polar flagellum. Bacteria with a DNA G+C content between 57.5 and 64.7 mol% were identified as members of the genus *Pseudomonas*. The remaining strains with a lower DNA G+C content (between 43 and 48 mol%) were affiliated to the genus *Alteromonas*. Four phenotypically distinguishable clusters were described as new species, i.e., *A. communis*, *A. vaga*, *A. macleodii* and *A. marinopraesens* (Baumann et al., 1972). *Alteromonas marinopraesens* was later renamed *A. haloplanktis* (Reichelt and Baumann, 1973).

DNA-rRNA and DNA-DNA hybridization experiments among *Alteromonas* species revealed the genetic heterogeneity of the genus *Alteromonas* and identified four distinct clusters: 1) *Alteromonas macleodii*; 2) the *Alteromonas haloplanktis* cluster, including the majority of *Alteromonas* species and some undescribed taxa, i.e., *A. haloplanktis*, *A. espejana*, *A. undina*, *A. rubra*, *A. luteoviolacea*, *A. citrea*, *A. aurantia*, and also “*Pseudomonas piscicida*,” “*Alteromonas thalassomethanolica*,” “*Pseudomonas marinoglutinosa*,” “*Pseudomonas nigrifaciens*,” “*Pseudomonas carrageenovora*,” “*Pseudomonas atlantica*” and a number of unidentified strains named “alginolytic bacteria”; 3) *A. putrefaciens* and *A. hanedai*; 4) *A. communis* and *A. vaga*, which formed a separate rRNA branch, and were excluded from *Alteromonas* to create a new genus of marine bacteria *Marinomonas* (Van Landschoot and DeLey, 1983). The latter group

differs from the first three groups in the inability to produce extracellular hydrolases and utilize glycerol, lactate, aromatic compounds and other carbon sources. Preliminary studies on the amino acid sequence composition of glutamine synthetase (Baumann and Baumann, 1980) and nucleotide divergence of ribosomal RNA (De Smedt et al., 1980) of *Alteromonas* species confirmed the distinct position of *A. communis* and *A. vaga*.

Pigmented heterotrophic *Alteromonas*-like bacteria have been isolated from the Mediterranean Sea coastal waters. Some of them produced the pigment violacein and revealed antibiotic activity. As the new violet-pigmented isolates differed from the violacein-containing *Chromobacterium* species in physiological and genetic properties, they were described as a new species, *Alteromonas luteoviolacea* (Gauthier, 1976b; Gauthier, 1982). The other antibiotic-producing isolates, characterized by the formation of different intracellular indiffusible red, orange and yellow pigments, were described as three novel *Alteromonas* species, i.e., *A. rubra*, *A. aurantia* and *A. citrea*, respectively (Gauthier, 1976a; Gauthier, 1977; Gauthier and Breittmayer, 1979).

Enger et al. (1987) investigated twelve aerobic Gram-negative prodigiosin-producing marine bacteria with a DNA G+C content of 37 mol%. The strains differed from known *Alteromonas* species in the ability to denitrify and in the possession of sheathed flagella. Despite their distinctive properties, all new isolates were included in the new species, *Alteromonas denitrificans* (Enger et al., 1987). It should be noted that cells with sheathed flagella were observed earlier in strains of *Pseudoalteromonas luteoviolacea* (Novic and Tyler, 1985).

Nonpigmented bacteria were described as *A. espejiana* and *A. undina* (Chan et al., 1978) and *A. hanedai* (Jensen et al., 1980). It is pertinent to note that *A. espejiana* was studied initially intensively because it was the host of an unusual lipid containing bacteriophage PM2 (Espejo and Canelo, 1968). *Alteromonas espejiana* produces the exonuclease BAL-31, phospholipase A, and lysophospholipase (Cadman and Eichberg, 1983; Wei et al., 1983).

Several pseudomonads with a low DNA mol% G+C content, including *P. atlantica*, *P. putrefaciens*, *P. piscicida* and *P. nigrifaciens* were included into *Alteromonas* as species *incertae sedis* (Baumann et al., 1984b). Yellow-pigmented bacteria causative of fish disease were originally identified as *Flavobacterium piscicida* (Bein, 1954), and described as *Pseudomonas piscicida* (Buck et al., 1963) when similar bacteria were later detected in seawater during the "red tide" of the microalgae *Gymnodium brevis*.

Pseudomonas nigrifaciens described earlier by White (1940) was reclassified as *A. nigrifaciens* (Baumann et al., 1984a). On the basis of 5S rRNA sequence analysis, *A. putrefaciens* (Lee et al., 1981) and *A. hanedai* (Jensen et al., 1980) were reclassified and assigned to the new genus *Shewanella* (MacDonell and Colwell, 1985).

DNA-rRNA hybridization were used to study the genotypic relationships between species of *Alteromonas*, *Pseudomonas* and other *Pseudomonas*-like bacteria. As a result of these experiments and supported by morphological, physiological, and biochemical properties and by DNA base composition, 11 strains of five *Pseudomonas* species (*P. atlantica*, *P. carrageenovora*, *P. marinoglutinosa*, *P. nigrifaciens* and *P. piscicida*) were assigned to the genus *Alteromonas* (De Vos et al., 1989). Though "*Pseudomonas atlantica*" and "*Pseudomonas carrageenovora*" were included in *Alteromonas*, their species status was not elucidated. Later, several aerobic Gram-negative polarly flagellated agar-decomposing bacteria were isolated from marine seaweeds collected in coastal waters of the Sea of Japan. On the basis of the phenotypic properties and DNA-DNA hybridization results of five newly isolated strains, *Pseudomonas atlantica* and *Pseudomonas carrageenovora* (capable of agar or carrageenan hydrolysis) were described as the new species *Alteromonas atlantica* and *Alteromonas carrageenovora*, respectively (Akagawa-Matsushita et al., 1992b).

The tetrodotoxin-synthesizing bacteria of *A. tetraodonis* were isolated from skin slime of the fish *Fugu poecilonotus*—a well-known producer of tetrodotoxin (Simidu et al., 1990). DNA-DNA hybridization experiments led to the reclassification of *A. tetraodonis* as *A. haloplanktis* subsp. *tetraodonis* and *A. haloplanktis* as *A. haloplanktis* subsp. *haloplanktis* (Akagawa-Matsushita et al., 1993), which were later included with *Pseudoalteromonas* (Gauthier et al., 1995). However, on the basis of the polyphasic taxonomic study, *P. haloplanktis* subsp. *tetraodonis* strain (originally described as *A. tetraodonis* by Simidu et al., 1990) was revived as an independent species *Pseudoalteromonas tetraodonis*, and *P. haloplanktis* subsp. *haloplanktis* was reclassified as *Pseudoalteromonas haloplanktis* (Ivanova et al., 2001c).

1995 to the Present

The fundamental systematic investigation of marine aerobic proteobacteria was published by G. Gauthier and coauthors (Gauthier et al., 1995). To characterize the intra- and intergeneric relationships of *Alteromonas* and related genera, small-subunit (16S) ribosomal RNA sequence

analysis was performed on 17 strains of *Alteromonas*, *Shewanella*, *Vibrio* and *Pseudomonas* species using three different phylogenetic algorithms. All species belong to the γ -3 subgroup of the class Proteobacteria. The molecular analysis confirmed the genetic heterogeneity of the genus *Alteromonas* and demonstrated the separate phylogenetic position of *Alteromonas macleodii* from the other species forming a monophyletic cluster. The new genus *Pseudoalteromonas* was proposed to include the remaining 11 earlier described *Alteromonas* species and *Pseudomonas piscicida*. On the basis of the phylogenetic study of Gauthier et al. (1995), *Pseudoalteromonas haloplanktis* ATCC 14393^T was described as a type strain and type species of the new genus. In addition, the following species were reclassified: *Pseudoalteromonas atlantica*, *Pseudoalteromonas aurantia*, *Pseudoalteromonas carrageenovora*, *Pseudoalteromonas citrea*, *Pseudoalteromonas denitrificans*, *Pseudoalteromonas espejiana*, *Pseudoalteromonas luteoviolacea*, *Pseudoalteromonas nigrifaciens*, *Pseudoalteromonas piscicida*, *Pseudoalteromonas rubra* and *Pseudoalteromonas undina*. The study pointed towards the presence of four monophyletic groups that were confirmed by different phylogenetic algorithms: 1) *Pseudoalteromonas denitrificans* as an outgroup species; 2) two pigmented species, *Pseudoalteromonas citrea* and *Pseudoalteromonas aurantia*; 3) three other pigmented species, *Pseudoalteromonas piscicida*, *Pseudoalteromonas rubra* and *Pseudoalteromonas luteoviolacea*; and 4) all nonpigmented *Pseudoalteromonas* species (Gauthier et al., 1995). Thus, the history of the two genera *Alteromonas* and *Pseudoalteromonas* is very closely interwoven (Table 1).

Alteromonas fuliginea and *A. distincta* (Romanenko et al., 1994b; Romanenko et al., 1995a) have been described as pigmented melanin-synthesizing *Alteromonas* species and were reclassified as *Pseudoalteromonas* species (Ivanova et al., 1998b; Ivanova et al., 2000a; Table 1).

The new species of encapsulated bacteria of *Alteromonas*, *A. elyakovii*, was described for a strain isolated from the mussel *Crenomytilus grayanus* inhabitant of the Peter the Great Bay, Sea of Japan (Ivanova et al., 1996b). *Alteromonas elyakovii* possessed highly active alkaline phosphatase and laminaranase (Fedosov et al., 1991; Sova et al., 1994). Bacteria with similar phen- and genotypic characteristics were isolated from spot-wounded fronds of *Laminaria japonica*, collected from the Sea of Japan (Sawabe et al., 1992). The *Laminaria* isolates were characterized by unique alginolytic activity and might be the causative agent of spot disease (Sawabe et al., 1997; Sawabe et al., 1998a). Phy-

logenetic investigations of strain *Alteromonas elyakovii* KMM 162 and the alginolytic strains showed that they belong to the same species *Pseudoalteromonas elyakovii* (Sawabe et al., 2000).

Bacteria associated with mollusks were described as the first marine isolates of *P. nigrifaciens* and the species description was emended (Ivanova et al., 1996a).

During the last years, the genus *Pseudoalteromonas* was enlarged with the new species *P. antarctica* (Bozal et al., 1997), *P. prydzensis* (Bowman, 1998a), *P. bacteriolytica* (Sawabe et al., 1998a), *P. tunicata* (Holmstrom et al., 1998), *P. peptidolytica* (Venkateswaran and Dohmoto, 2000) and *P. ulvae* (Egan et al., 2001).

Besides the description of the new species, the literature indicates the presence of additional species, which, however, have not been validly described. Andrykovitch and Marx (1988) reported on the isolation of the new melanin-synthesizing bacterium "2-40" associated with the alga *Spartina alterniflora*, which is able to hydrolyze agar and other polysaccharides. The tyrosinase from strain 2-40 has been characterized (Kelley et al., 1990). According to its physiological and biochemical properties and its DNA G+C content of 45.6 mol%, strain 2-40 was assigned to the genus *Alteromonas*, but not identified at the species level. Analysis of the 16S ribosomal DNA sequence demonstrated that the bacterium probably represents the type of a new hitherto undescribed genus (Gonzalez and Weiner, 2000).

In 1993, the yellow-gray pigmented "*Alteromonas rava*" sp. nov. [inv.] synthesizing the new antibiotics "thiomarinols" was described (Kodama et al., 1993; Shiozawa et al., 1993; Shiozawa and Takahashi, 1994), but currently the species has not yet been validated.

A mesophilic heterotrophic bacterium, isolated from a seawater sample collected near a deep-sea hydrothermal vent, was identified as *Alteromonas macleodii* according to its morphological, physiological, biochemical and genotypical properties (Raguenes et al., 1996). Analysis of 16S rDNA confirmed the phylogenetic similarity, which was further substantiated by a DNA-DNA reassociation of 82%. The authors classified the new bacterium as *A. macleodii* subsp. *fijiensis* on the basis of the following findings: DNA-DNA relatedness level lower than 90% but higher than 70%; metabolic differences between the type and the new strain; the ability of the new bacterium to produce acidic exopolysaccharide with novel properties; and the isolation source of the new bacterium, which is a deep-sea hydrothermal vent, depth 2000 m (Raguenes et al., 1996). However, the subspecies name *fijiensis* has yet not been validated.

Table 1. List of *Alteromonas* bacteria reclassified as valid species of *Pseudoalteromonas* or other genera.

Raguene et al. (1997) proposed a new *Alteromonas* species, *Alteromonas infernus*, for a deep-sea polysaccharide-producing bacterium. The new strain was isolated from a sample of fluid collected from the surface of the vestimentiferan worm *Riftia pachyptila*, which inhabits sites near hydrothermal vents. Morphological and physiological properties of these bacteria

were similar to those of *Alteromonas macleodii*, e.g., rod-shaped cells motile by means of a single polar flagellum. The DNA G+C content was 48 mol%. The level of the DNA-DNA reassociation between the new bacterium and *A. macleodii* was 48%, indicating that the new isolate may indeed constitute a new species of *Alteromonas* (Raguene et al., 1997). *Alteromonas infernus*,

however, has not yet been included in the Validation Lists.

Genus *Alteromonas*

Phylogeny

The results of phylogenetic analysis, based on 16S rDNA sequence, revealed *Alteromonas macleodii* belongs to the γ -3 subgroup of the class Proteobacteria. It forms a monophyletic taxon that is distinct from *Pseudoalteromonas*, with which it shares 88% sequence similarity only (Gauthier et al., 1995; Fig. 1). Intergeneric DNA-DNA similarities obtained for *Alteromonas macleodii* and species of some related genera were at the level of 5–12% (Table 2).

Taxonomy

The genus *Alteromonas* (originally described by Baumann et al., 1972, to accommodate aerobic, Gram-negative, nonpigmented, polarly flagellated, obligately marine bacteria with DNA G+C content of 38–50 mol%) was divided into two genera: *Alteromonas* with a single species, *A. macleodii*, and *Pseudoalteromonas*, including 11 species previously belonging to *Alteromonas* (Gauthier et al., 1995). The type species is *Alteromonas macleodii*, with the type strain ATCC 27126^T (= strain 107 of Baumann et al. 1972).

Habitat

Alteromonas macleodii strains were isolated originally from seawater samples collected in the

area of the Hawaiian archipelago (Baumann et al., 1972). *Alteromonas macleodii* subsp. *fijiensis* and *Alteromonas infernus* strains are inhabitants of deep-sea environments and have been detected in deep-seawater sample and from surface of the vestimentiferan worm *Riftia pachyptila*, which inhabits sites near hydrothermal vents (Raguenes et al., 1996; Raguenes et al., 1997).

Physiology

Alteromonas macleodii is a Gram-negative, strictly aerobic, chemoorganotrophic, oxidase positive and catalase negative, nonsporeforming straight rod, 0.7–1 µm in diameter and 2–3 µm long, motile by single unsheathed polar flagellum, not luminescent and nonpigmented. Strains grow at 20–35°C, some strains at 37–40°C, but not at 4°C. They are able to produce extracellular amylase, gelatinase, and lipase, but not chitinase. Also, they utilize a broad range of organic compounds, including hexoses, disaccharides, sugar acids and amino acids. Strains do not denitrify and do not produce arginine dihydrolase. Poly-β-hydroxybutyrate is accumulated. Bacteria require a seawater base for growth, but not organic growth factors. The G+C content of the DNA is 44.9–46.4 mol% (Baumann et al., 1972; Baumann et al., 1984a; Baumann et al., 1984b; Gauthier et al., 1995), and that of “*Alteromonas infernus*” is 48 mol% (Raguenes et al., 1997).

Phenotypically, *A. macleodii* strains differ from pseudoalteromonads by the ability to utilize as the sole source of carbon and energy a broad spectrum of substrates, including sucrose, cellobiose, melibiose, lactose, D-ribose, L-rhamnose, turanose, salicin, D-gluconate, DL-glycerate, L-valine and L-ornithine (Baumann et al., 1972; Baumann et al., 1984a; Gauthier et al., 1995). The main phenotypic differentiating characteristics of *Alteromonas macleodii*, *Glaciecola* and *Pseudoalteromonas* species are listed in Table 3.

Genus *Pseudoalteromonas*

Phylogeny

The phylogenetic structure of *Pseudoalteromonas* (Fig. 2) indicates that most of the nonpigmented species are closely related and constitute the major cluster of the genus. *Pseudoalteromonas antarctica*, *P. nigrifaciens*, *P. undina*, *P. atlantica*, *P. carrageenovora*, *P. elyakovii* and *P. distincta* are closely related to *P. haloplanktis* (99.4–99.9% sequence similarity). The pairs *P. elyakovii*–*P. distincta* and *P. haloplanktis*–*P. nigrifaciens* share almost identical 16S rDNA sequences. Also, the two pigmented species *P. citrea* and *P. aurantia* are highly related and form a separate subline, distant from *P. haloplanktis* and other nonpigmented species (97.5–97.6% sequence similarity). The recently described dark-purple pigmented species *P. ulvae* was

Symbols: +, positive test reaction; –, negative test reaction; V, variable results between species; V+, variable results between strains, type strain is positive; V–, variable results between strains, type strain is negative; W, weak or delayed reaction; and ND, not determined.

^aAll strains were positive for the following tests: motility, sodium ions requirement for growth, oxidase, growth in 1–3% NaCl, growth at 7–20°C; all strains were negative for arginine dihydrolase production.

^bData from Baumann et al. (1984a, b).

^cData from Bowman et al. (1998c).

found to show 97% similarity to other *Pseudoalteromonas* species (Egan et al., 2001). *Pseudoalteromonas prydzensis* forms a subcluster distinct from both the nonpigmented and pigmented species (97.3–97.7% and 95.0–95.8% sequence similarity, respectively). *Pseudoalteromonas peptidolytica* is most similar to *P. piscicida* (99.1% sequence similarity), which, together with *P. luteoviolacea* and *P. rubra*, constitute a separate subcluster among the pigmented *Pseudoalteromonas* species. *Pseudoalteromonas*

denitrificans and *P. tunicata* constitute individual deep clades within the genus *Pseudoalteromonas*. With 90.6–91.0% sequence similarities with other *Pseudoalteromonas* species, *P. bacteriolytica* constitutes the deepest branch within the genus.

Also included in Fig. 2 is the phylogenetic position of novel *Pseudoalteromonas* species, including *P. ruthenica*, *P. flavipulchra*, *P. maricaloris*, *P. issachenkonii* (Ivanova et al., 2002a; Ivanova et al., 2002b; Ivanova et al., 2002c), *P.*

Fig. 2. Phylogenetic structure of the genus *Pseudoalteromonas*. Bootstrap values are given to confirm the topology of unrooted dendrogram.

paragorgicola and *P. translucida* which will be published in the near future.

Taxonomy

At the present time, *Pseudoalteromonas* genus contains 27 validly described species, including reclassified former *Alteromonas* species, listed in Table 1, and recently described *Pseudoalteromonas* species (Bozal et al., 1997; Bowman, 1998a; Holmstrom et al., 1998; Sawabe et al., 1998a; Venkateswaran and Dohmoto, 2000; Egan et al., 2001; Ivanova et al., 2002a; Ivanova et al., 2002b; Ivanova et al., 2002c).

Habitat

Bacteria of the genus *Pseudoalteromonas* are obligate and widespread inhabitants of marine environments and have been isolated from diverse marine sources from various geographical regions of the world's oceans (Table 4).

Physiology

Pseudoalteromonas strains are aerobic, Gram-negative, nonsporeforming, straight or slightly curved, rod-shaped bacteria $0.2\text{--}1.5\ \mu\text{m} \times 1.8\text{--}4.0\ \mu\text{m}$. Strains of most species are motile by means of a single unsheathed polar flagellum.

Sheathed flagella have been reported for *P. luteoviolacea*, *P. denitrificans* (Novic and Tyler, 1985; Enger et al., 1987) and *P. tunicata* (Holmstrom et al., 1998). *Pseudoalteromonas denitrificans* may produce a tuft of 2–3 flagella at one pole. *Pseudoalteromonas distincta* is characterized by both a single polar and 3–7 lateral flagella (Fig. 3a). Cells of *P. antarctica* have been observed to form filaments up to $10\ \mu\text{m}$ long (Bozal et al., 1997). Peritrichous flagellation had been originally noted for *P. piscicida* (Bein, 1954). The bacteria of *P. nigrifaciens* (Fig. 3b, c) and *P. elyakovii* (Fig. 3d) are able to form capsules (Ivanova et al., 1996a; Ivanova et al., 1996b; Sawabe et al., 2000).

The bacteria are oxidase positive, and catalase positive or weakly positive. They do not accumulate poly- β -hydroxybutyrate and show no arginine dihydrolase activity. *Pseudoalteromonas* are chemoorganotrophs with a respiratory type of metabolism. *Pseudoalteromonas tunicata* and *P. ulvae* are described as a facultative anaerobic bacteria (Holmstrom et al., 1998; Egan et al., 2001). *Pseudoalteromonas denitrificans* is able to denitrify (Enger et al., 1987). *Pseudoalteromonas denitrificans* and only some *P. haloplanktis* strains form nitrite from nitrates. Some pigmented species need additional organic factors for growth. All species grow at $20\text{--}25^\circ\text{C}$. Most species are able to grow at 4°C . Growth from 0

Fig. 3. Transmission electronic micrographs of *Pseudoalteromonas distincta* KMM 638^T (a), *Pseudoalteromonas nigrifaciens* KMM 158 (b), KMM 156 (c), and *Pseudoalteromonas elyakovii* KMM 162^T (d). (a) Cell with polar and lateral flagella, $\times 20,000$; (b, c, and d) Cells with single polar flagellum and capsules, b, d, $\times 30,000$, and c, $\times 40,000$.

to 30°C was noted for *P. prydzensis* (Bowman, 1998a). *Pseudoalteromonas aurantia*, *P. undina*, *P. prydzensis*, *P. denitrificans*, *P. antarctica*, *P. tunicata*, *P. ulvae*, some strains of *P. nigrifaciens* and of *P. espejiana* do not grow at 35°C. Several species such as *P. piscicida*, *P. elyakovii* (some strains only) and *P. peptidolytica* grow at 37°C. Except for *P. peptidolytica* (Venkateswaran and Dohmoto, 2000), none of the species grows at 40°C.

Several studies have shown that sodium ions are essential for alteromonad-like bacteria

(MacLeod and Hori, 1960; MacLeod, 1968). Considering the marine origin and sodium ion requirement for growth, *Pseudoalteromonas* strains could be regarded as obligately marine microorganisms. All species need seawater or sodium ions for growth and the most of them grow in 3–6% NaCl. For *P. ulvae*, 1–2% NaCl is required for growth (Egan et al., 2001). Several species are able to grow in 10% NaCl. *Pseudoalteromonas antarctica* and *P. prydzensis* tolerate up to 12.5 and 15% NaCl, respectively. The genus consists mainly of species isolated

from marine environments, and they have not been detected from terrestrial and some other sources with the exception of the *P. nigrifaciens* type strain, isolated from salted butter (White, 1940).

Pigmented species are able to produce intracellular insoluble noncarotenoid pigments and melanin-like pigments (Table 4) and synthesize high molecular weight substances with autotoxic and antibiotic effects against Gram-positive and Gram-negative bacteria. The antibiotic substance from cells of *P. rubra* has been shown to be a complex membrane-bound glycoprotein (Ballester et al., 1977). *Pseudoalteromonas citrea* produces two polyanionic antibiotic compounds (Gauthier, 1977). Two brominated antibacterial products and polyanionic polysaccharides inhibiting the growth of Gram-positive, and to lesser extent, Gram-negative bacteria, as well as the protozoan *Paramecium caudatum*, were isolated from *P. luteoviolacea* (Gauthier and Flatau, 1976c; Kamei et al., 1986).

Pseudoalteromonads utilize a variety of organic compounds as sole sources of carbon and energy, including carbohydrates, monocarboxylic acids and amino acids, and it should be noted that utilization of carbon sources varies between species and strains within some species (Tables 5 and 6). The majority of *Pseudoalteromonas* species is characterized by high hydrolytic activities and produces gelatinase, lipase, caseinase, lecithinase and DNases; they utilize D-glucose as a sole carbon source, but are negative for utilization of D-ribose, L-rhamnose, turanose, salicin, glucuronate, DL-glycerate, erythritol, sorbitol, *meso*-inositol, adonitol, L-valine, L-ornithine and *m*-hydroxybenzoate. *Pseudoalteromonas distincta* does not utilize D-glucose and other carbohydrates. Some species display amylase, alginase and chitinase activities. *Pseudoalteromonas atlantica* and *P. carrageenovora* (Akagawa-Matsushita et al., 1992b) and some strains of *P. citrea* (Ivanova et al., 1998b) are able to degrade agar and/or carrageenan. Most members of *Pseudoalteromonas* are resistant to the O/129 vibriostatic agent (2,4-diamino-6,7-diisopropyl pteridine sulfate or phosphate; (Gauthier and Breittmayer, 1992) and also to penicillin, polymyxin, lincomycin and oleandomycin (Ivanova et al., 2001b). Penicillin-sensitive *P. antarctica* strains were noted by Bozal et al. (1997); *P. tunicata* and *P. ulvae* are susceptible to O/129 (Holmstrom et al., 1998; Egan et al., 2001).

The phenotypic features of the new *Pseudoalteromonas* species, *P. ruthenica*, *P. flavipulchra*, *P. maricaloris*, *P. paragorgicola*, *P. translucida* (Ivanova et al., 2002a, b, c) and *P. issachenkonii* and *P. translucida* which will be published in the near future, are presented in Table 6.

Genomic Relatedness

The G+C contents in the DNA of *Pseudoalteromonas* bacteria range from 37 mol% (*P. denitrificans*) to 44–46 mol% (*P. bacteriolytica*) and 46–48 mol% (*P. rubra* and *P. ruthenica*; Tables 5 and 6). DNA-DNA hybridization studies revealed interspecies relatedness between most of the *Pseudoalteromonas* species at level of 20–40% (Table 2). Though some species revealed higher DNA-DNA reassociation, namely, *P. haloplanktis* and *P. undina* (54%), *P. espejiana* and *P. atlantica* (54%), *P. tetraodonis* and *P. carrageenovora* (58%), *P. distincta* and *P. elyakovii* (61%). *Pseudoalteromonas prydzensis* had low DNA-DNA reassociation levels (10–28%) with the other nonpigmented pseudoalteromonads (Bowman, 1998a). Supporting low 16S rDNA similarities, *P. bacteriolytica* and *P. peptidolytica* were most distantly related (2–6% DNA-DNA relatedness as determined by using a fluorometric direct binding method) to the pigmented *Pseudoalteromonas* species (Sawabe et al., 1998a; Venkateswaran and Dohmoto, 2000).

Genus *Glaciecola*

Phylogeny

The genus *Glaciecola* forms a separate 16S rDNA lineage within the γ -subclass of Proteobacteria, and is distantly related to *Alteromonas macleodii* (89.7–92.1% sequence similarity; Bowman et al., 1998c).

Taxonomy

The genus *Glaciecola* was proposed by Bowman et al. (1998c) for two groups of isolates originating from sea-ice diatom assemblages collected from coastal area of eastern Antarctica. The genus is defined as rod-shaped or slightly curved, curved or spiral cells which are Gram negative, oxidase- and catalase positive, motile, nonsporulating, strictly aerobic, chemoheterotrophic, psychrophilic and slightly halophilic, and require seawater for growth. Major fatty acids are hexadecaenoic acid (16:1 ω 7c), hexadecanoic acid (16:0) and octadecaenoic acid (18:1 ω 7c). The DNA G+C content is 40–46 mol% (determined by the thermal denaturation method). The type species is *Glaciecola punicea* ACAM 611^T.

The *Glaciecola* genus comprises two species, the type species *Glaciecola punicea*, type strain ACAM 611^T, and *Glaciecola pallidula*, type strain ACAM 615^T, which differ from each other in phenotypic features (Table 7), DNA-DNA hybridization, and phylogenetic data. The fatty acid profiles of *Glaciecola* strains are very similar

^aAll strains were positive for the following tests: growth at 0–10°C; growth on marine 2216 agar, R2A seawater agar and ZoBell's agar; production of catalase, cytochrome-*c* oxidase; α-galactosidase and β-galactosidase; acid production (weak and/or delayed) from D-glucose, D-galactose, D-melibiose and glycerol; and utilization of oxaloacetate as a sole carbon and energy source. All strains were negative for the following tests: growth at 25°C and higher; growth with 3× and 4× strength seawater, tolerance to 5% ox bile salts; nitrate as a nitrogen source; nitrate reduction, denitrification and nitrogen fixation; hydrolysis of urea, xanthine, egg yolk, casein, gelatin, chitin, dextran and DNA; production of L-phenylalanine deaminase, L-tryptophan deaminase, arginine dihydrolase, glutamate decarboxylase, lysine decarboxylase, ornithine decarboxylase, α-glucosidase, β-glucosidase, α-fucosidase, α-arabinosidase, β-glucuronidase, β-N-acetylglucosaminidase; indole from L-tryptophan; hydrogen sulfide from thiosulfate; acid production from L-arabinose, D-mannose, D-fructose, L-rhamnose, D-xylose, D-mannitol, N-acetylglucosamine, sucrose, lactose, cellobiose, trehalose, D-raffinose, dextran, adonitol, L-arabitol, D-sorbitol and *m*-inositol; utilization of N-acetylglucosamine, L-arabinose, cellobiose, D-xylose, L-rhamnose, D-fructose, D-galactose, D-glucose, D-mannose, lactose, maltose, D-melibiose, D-raffinose, sucrose, trehalose, starch, chitin, adonitol, L-arabitol, *i*-erythritol, *m*-inositol, D-mannitol, D-sorbitol, D-gluconate, D-glucuronate, saccharate, propionate, isobutyrate, valerate, isovalerate, caproate, heptanoate, nonanoate, malonate, adipate, glutarate, pimelate, azelate, *trans*-aconitate, citrate, 3-hydroxybutyrate, 2-oxoglutarate, L-alanine, L-asparagine, L-aspartate, L-histidine, L-leucine, L-phenylalanine, hydroxy-L-proline, L-ornithine, L-serine, L-threonine, putrescine, γ-aminobutyrate and urate.

^bNumbers of strains studied.

^cMeasured by T_m.

Data from Bowman et al. (1998c).

to the whole-cell fatty acid profile of *Alteromonas macleodii*, but substantially more enriched in monounsaturated fatty acids (Bowman et al., 1998c; Table 8).

Habitat

Antarctic sea-ice diatom assemblages are the only known habitat (Bowman et al., 1998c).

Physiology

Glaciecola strains are psychrophilic, able to grow at temperature from –2 to 20°C. Most *G. punicea* strains grow slowly at 25°C but not at higher temperatures. *Alteromonas* species, the closest relatives, have a mesophilic growth temperature range, are more halotolerant, and versatile in

respect to carbon source utilization and extracellular enzyme production (Table 3). *Glaciecola* strains are distinguished from the other marine chemoheterotrophs belonging to the γ-Proteobacteria including *Colwellia*, *Pseudoalteromonas*, *Alteromonas* and *Shewanella* by phenotypic features (Table 9).

Genomic Relatedness

The DNA G+C contents of *G. punicea* and *G. pallidula* strains are 44–46 mol% and 40 mol%, respectively. *Glaciecola punicea* strains exhibit high DNA-DNA reassociation levels of 82–95% among each other, and low DNA reassociation with strains of *G. pallidula* (10–19%). DNA-DNA hybridization levels between *A. macleodii*, *G. punicea* and *G. pallidula* strains were 13 and 10%, respectively (Bowman et al., 1998c).

Genus *Idiomarina*

Introduction

Two strains, KMM 227^T and KMM 231^T, were isolated from seawater sampled at depths of 4000 and 5000 m, respectively, in the northwestern part of the Pacific Ocean. The new isolates were similar in their phenotypic properties to other marine aerobic proteobacteria, including *Alteromonas*, *Pseudoalteromonas* and *Marinomonas*, but they were characterized by several salient differences from known genera: morphological peculiarities, inability to use carbohydrates as the sole source of carbon and energy, and unusual cellular fatty acid composition. On the basis of phenotypic, chemotaxonomic and phylogenetic data, these marine deep-sea bacteria were classified as *Idiomarina abyssalis* and *Idiomarina zobellii* (Ivanova et al., 2000b).

Phylogeny

Comparative 16S rDNA sequence analysis of *Idiomarina* strains KMM 227 and KMM 231 showed both strains to be similar (sequence similarity 96.9%). They formed a separate monophyletic branch within the γ -subclass of Proteobacteria, and are distantly related to

Alteromonas, *Colwellia* and *Pseudoalteromonas*. *Colwellia psychrerythraea* was found to be the nearest relative to *Idiomarina* KMM 227^T and KMM 231 (90.5 and 90.1% 16S rDNA sequence similarities, respectively; (Ivanova et al., 2000b; Fig. 1).

Taxonomy

The genus *Idiomarina* was proposed to accommodate strictly aerobic, Gram-negative, psychrotolerant heterotrophic halophilic, marine deep-sea microorganisms with a respiratory type of metabolism. The bacteria require NaCl for growth. The genus includes the type species *Idiomarina abyssalis* KMM 227^T and *Idiomarina zobellii* KMM 231^T (Ivanova et al., 2000b). *Idiomarina abyssalis* forms an outer sheath-like structures covering one of the cell poles (Fig. 4a, b). It grows in 0.6–15% NaCl, produces proteinase, and oxidizes cyclodextran, dextran, glycogen, methylpyruvate, monomethylsuccinate, acetate, glycyl-L-glutamic acid, L-proline, glycerol, and glucose-6-phosphate. The G+C content in the DNA is 50 mol%. *Idiomarina zobellii* is characterized by growth in 1–10% NaCl, ability to form long fimbria along with a polar flagellum (Fig. 4c), production of chitinase, and

(a, b) Cells of KMM 227^T with polar flagella and outer sheath-like structures ballooning over one pole; (c) Cell of KMM 231^T with fimbria (indicated by arrow) along with a flagellum at one pole.

monomethylsuccinate, glycyl-L-glutamic acid, and L-ornithine utilization. It does not utilize cyclodextran, dextran, glycogen, L-proline, acetate, glycerol, and glucose-6-phosphate and produce proteinase. The G+C content in the DNA is 48 mol%. Comparative characterization of *I. abyssalis* and *I. zobellii* species are shown in Table 10.

Habitat

At present, the only known habitat of *Idiomarina* bacteria is deep-sea water (depths of 4000–5000 m), in the Pacific Ocean.

Genomic Relatedness

The DNA-DNA reassociation levels between the strains were determined to be as follows: *I. abyssalis* KMM 227^T and *I. zobellii* KMM 231^T—27%; *I. abyssalis* KMM 227^T and other species: *Alteromonas macleodii*—7%; *Vibrio cholerae*—7%; *Aeromonas jandai*—3%; *Marinomonas communis*—7%; *Pseudoalteromonas haloplanktis*—6%; and *Escherichia coli*—3%.

Physiology

The genus *Idiomarina* comprises Gram-negative, strictly aerobic, chemoorganotrophic, oxidase-

^aBacteria are positive for the following tests: sodium ion requirement for growth, growth at 30°C, motility by using a single polar flagellum, oxidase, production of lipase, DNase, gelatin liquefaction; are negative for growth at 40°C, indole reaction, nitrate reduction, denitrification, arginine dihydrolase, and acid production from carbohydrates.

positive, asporogenic, motile by one polar flagellum, rod-shaped, single, and sometimes paired cells of 0.7–0.9 µm in diameter. Bacteria may have fimbria and are able to form external sheath-like structures on the one pole of the cells. They do not accumulate poly-β-hydroxybutyrate as a reserve product and have no arginine dihydrolase. The bacteria do not need organic growth factors but require seawater or 0.6–15% NaCl for growth. They grow at 4–35°C, with an optimum at 20–25°C, but do not grow at 40°C. Growth occurs at pH 5.5–9.5, with the optimum pH being 7.5–8.5. They produce gelatinases, lipases, and DNases. *Idiomarina abyssalis* produces proteinase. Strains do not hydrolyze starch and agar. The following substrates are utilized: D-arginine, L-tyrosine, L-alanine, alaninamide, L-alanine-glycine, α-ketobutyrate, and α-ketovalerate. Bacteria do not utilize D-arabinose, D-rhamnose, D-mannose, sucrose, maltose, lactose, melibiose, glycerol, mannitol, L-lysine, and L-phenylalanine. Bacteria are sensitive to erythromycin, and tolerant to kanamycin, ampicillin, benzylpenicillin, oleandomycin, lincomycin, tetracycline, oxacillin, vancomycin, and vibriostatic substance O/129. Iso-branched fatty acids with the odd number of carbon atoms predominate (up to 70%), and saturated and monounsaturated fatty acids are detected in cellular fatty acid composition of *Idiomarina* strains.

Idiomarina strains are similar in their properties to members of *Alteromonas*, *Pseudoalteromonas*, *Marinomonas*, *Halomonas* and *Oceanospirillum*. Representatives of related *Alteromonas* and *Pseudoalteromonas* genera differ from *Idiomarina* strains by lower DNA G+C content values, ability to utilize a broad spectrum

of carbon compounds, predominance of saturated and monounsaturated cellular fatty acids (Ivanova et al., 2000b). *Marinomonas* species have specific physiological and biochemical properties and a bipolar type of flagellation (Gauthier and Breittmayer, 1992). *Halomonas* species are characterized by tolerance to high concentration of sodium ions, a DNA G+C content of 57–68 mol%, peritrichous flagella and a specific fatty acid pattern (Dobson and Franzmann, 1996). Distinctive features of *Oceanospirillum* are specific cell morphology and phenotypic properties (Krieg, 1984). The main characteristics differentiating *Idiomarina* species from related genera are shown in Table 11.

Genus *Colwellia*

Introduction

Abyssal ocean depths (1000–6000 m) are characterized by temperatures <4°C and hydrostatic pressure of 400–600 atm. Bacteria adapted to these conditions can be expected to be psychrophilic, barophilic or barotolerant (ZoBell, 1946; ZoBell and Morita, 1957; Morita, 1975). Deep-sea microorganisms were isolated from many deep-sea samples, including invertebrate amphipods (Yayanos et al., 1979; Yayanos, 1989), intestinal tract of benthic animals (Deming and Colwell, 1982), bottom deposits and seawater (Jannasch et al., 1982; Deming, 1985). Representatives of microbial populations dwelling at ultra-abyssal depths from 6000 up to 11,000 m in the world's oceans are the least investigated deep-sea microorganisms.

Barophilic strain BNL-1 were isolated by Deming and coauthors from a seawater sample obtained at a depth of 7410 m in the Puerto Rico Basin of the Atlantic Ocean. Bacteria grew at 2°C and pressure of 740 atm. Pheno- and genotypic characteristics together with the 5S ribosomal RNA sequence analysis confirmed its difference from the other marine proteobacteria and revealed phylogenetic similarity to both the marine psychrophilic bacterium *Vibrio psychroerythrus* (D'Aoust and Kushner, 1972) isolated from shelf waters, and the deep-sea barophilic *Shewanella benthica* (MacDonell and Colwell, 1985). On the basis of the data obtained, strain BNL-1 was described as *Colwellia hadaliensis*, whereas *Vibrio psychroerythrus* was reclassified as *Colwellia psychroerythrus* comb. nov. (Deming et al., 1988). The epithet “*psychroerythrus*” has been changed to “*psychrerythraea*” (Euzéby, 1998).

^aStrains or genera: 1, *I. abyssalis* KMM 227^T; 2, *I. zobellii* KMM 231^T; 3, *Alteromonas*; 4, *Colwellia*; 5, *Halomonas*; 6, *Marinomonas*; 7, *Oceanospirillum*; and 8, *Pseudoalteromonas*.

Data obtained from D'Aoust and Kushner (1972), Baumann et al. (1984a, b), Krieg (1984), Vreeland et al. (1980), Deming et al. (1988), Bowman et al. (1998b), and Ivanova et al. (2000b).

with diatom algae assemblages of the Antarctic sea ice, Bowman and coauthors identified eight isolates similar to *Colwellia* strains. The isolates were psychrophilic and facultatively anaerobic, nonpigmented bacteria, growing in seawater, and able to synthesize ω3 polyunsaturated fatty acid docosahexaenoic acid, DHA, (0.7–8.0% of the total fatty acid amount). DNA-DNA hybridization similarities revealed the new Antarctic isolates form five distinct genospecies including *Colwellia psychrerythraea*. Thus, four new species of Antarctic DHA-producing bacteria have been described, i.e., *Colwellia demingiae*, *Colwellia psychrotropica*, *Colwellia rossensis* and *Colwellia hornerae* (Bowman et al., 1998b).

Phylogenetic, cultural, chemotaxonomic and enzymological properties (Takada et al., 1979) on the psychrophilic bacterium *Vibrio* sp. ABE-1, isolated from marine environment, allowed this strain to be identified as a new species of *Colwellia*, *C. maris* (Yumoto et al., 1998).

Phylogeny

16S rDNA sequence analysis showed 95.2–100% similarity between *Colwellia demingiae*, *Colwellia psychrotropica*, *Colwellia rossensis*, *Colwellia hornerae* and *Colwellia psychrerythraea* (96–97% sequence similarity). *Alteromonas macleodii*, *Glaciecola* and *Pseudoalteromonas* species were moderately related to *Colwellia* species (87–89% similarity; Bowman et al., 1998b). The 16S rDNA sequence analysis of *Colwellia maris* ABE-1^T revealed 92.9% similarity to *C. psychrerythraea* and 97.8% similarity to *C. rossensis*, while only low similarities were found with strains of *Pseudoalteromonas*, *Alteromonas*, *Shewanella*, *Photobacterium*, *Vibrio*, *Moritella*, *Escherichia* and *Aeromonas* (less than 90%).

Taxonomy

The genus *Colwellia* was proposed by Deming et al. (1988) for curved or straight rod-shaped

(0.5–1.0 μm in diameter and 2.5–5.0 μm in length), Gram-negative, asporogenic, motile by polar flagella, catalase- and oxidase-positive, chemoorganotrophic, facultative anaerobic microorganisms, associated with deep marine environments. All strains are able to synthesize docosahexaenoic acid, and the DNA G+C content is 40–46 mol%. The type species *Colwellia psychrerythraea* is red-pigmented and psychrophilic. Currently the genus *Colwellia* comprises seven species, including *Colwellia psychrerythraea*, *Colwellia hadaliensis* (Deming et al., 1988), *Colwellia demingiae*, *Colwellia rossensis*, *Colwellia hornerae*, *Colwellia psychrotropica* (Bowman et al., 1998b) and *Colwellia maris* (Yumoto et al., 1998).

Habitat

Colwellia strains have been isolated from organic materials and coastal marine water samples collected offshore from the United States (DeLong et al., 1993; Suzuki et al., 1997) and Marianas Trench (DeLong and Yayanos, 1986); Antarctic meromictic lake, Antarctic sea ice and water samples (Gosink and Staley, 1995; Bowman et al., 1998b); and cold coastal waters near Hokkaido, the Sea of Japan (Yumoto et al., 1998). *Colwellia* species are common inhabitants of the cold sea environments and have not been isolated from any other environments.

Physiology

Members of *Colwellia* are psychrophilic with an growth temperature at $<15^{\circ}\text{C}$, requiring sodium and magnesium ions for growth. Bacteria may be barophilic; *C. hadaliensis* is obligately barophilic. *Colwellia rossensis* forms intracellular gas vesicles. Most strains are capable of synthesizing $\omega 3$ polyunsaturated fatty acid docosahexaenoic acid (22:6 $\omega 3$; 0.7–8.0% of total fatty acids). All strains reduce nitrate to nitrite and degrade chitin and starch under aerobic conditions. Carbohydrate oxidation, fermentation of *N*-acetylglucosamine, chitin and D-glucose, and hydrolysis of other substrates are varied between *Colwellia* strains and species. The main phenotypic properties for differentiation of Antarctic *Colwellia* species and *Colwellia psychrerythraea* are listed in Table 12.

Colwellia maris has characteristic features and can be differentiated from other *Colwellia* species in its inability to ferment glucose and hydrolyze chitin, its gelatinase and DNase production, and unique synthesis of 9-*trans*-hexadecenoic acid (Table 13). Yumoto and coauthors reported that *C. psychrerythraea* did not generally produce acid from D-glucose under aerobic or anaerobic conditions for as long as 1 month, but acid was occasionally produced under aerobic conditions. The definition of *Colwellia* should

thus be amended with respect to D-glucose metabolism (Yumoto et al., 1998).

Genomic Relatedness

The DNA G+C content of the most *Colwellia* species range from 35 to 42 mol% (Table 13). A higher DNA G+C content of 45.7 mol% has been noted for *C. hadaliensis*. The DNA-DNA reassociation levels between *Colwellia* species were found to be as follows: 35–40% reassociation between *C. psychrerythraea* and *C. demingiae*; 12–24% between *C. psychrerythraea* and *C. rossensis*, *C. hornerae* and *C. psychrotropica* (Bowman et al., 1998b); and 22% between *C. psychrerythraea* and *C. maris* (Yumoto et al., 1998).

Chemotaxonomic Characterization

Carbohydrate-containing Biopolymers of *Pseudoalteromonas* Species

Structural investigations of polysaccharides (PSs) of several *Pseudoalteromonas* strains established a primary structure of repeating units of PSs in *P. nigrifaciens*, *Pseudoalteromonas* spp., and *P. elyakovii* (Gorshkova et al., 1993; Gorshkova et al., 1997; Gorshkova et al., 1998a; Gorshkova et al., 1998b; Nazarenko et al., 1993a; Nazarenko et al., 1993b; Nazarenko et al., 1999). The capsulated representatives of *Pseudoalteromonas* were described by Ivanova et al. (Ivanova, 1994a; Ivanova, 1996a). Capsular polysaccharides contained fucose, rhamnose, mannose, glucose, galactose, galactosamine, glucosamine, heptose, 3-deoxy-2-octulosonic acid and uronic acid. Chemical and physicochemical methods (mainly high-resolution NMR spectroscopy) revealed that capsular and cellular antigenic PSs had an identical structure (with the exception of those in *P. elyakovii*).

Pseudoalteromonas nigrifaciens strains, isolated from mollusks inhabiting the Sea of Japan, contain an unusual capsular PS structure composed of tetrasaccharide repeating units containing D-galactose, 3-*O*-acetyl-2-acetamido-2-deoxy-D-glucose, 2-acetamido-2-deoxy-L-guluronic acid and 3,6-dideoxy-3-(4-hydroxybutyramido)-D-galactose (Fuc3NR) residues. The structure of the repeating unit is as follows:

where R is $-\text{CO}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{OH}$

The following tests were all negative: Fe(III) reduction; trimethylamine N-oxide (TMAO) reduction, growth on 0–25% sea salts or ≥400% sea salts, hydrolysis of *o*-nitrophenyl-β-D-galactopyranoside (ONPG), DNA and dextran, arginine dihydrolase, lysine decarboxylase and ornithine decarboxylase activity, production of indole from L-tryptophan, H₂S production, production of acid from arabinose, xylose, melibiose, fructose, lactose, mannitol, sorbitol, inositol, mannose, mannose, sucrose and trehalose, and utilization of D-galactose, D-xylose, cellobiose, lactose, maltose, D-melibiose, trehalose, sucrose, L-raffinose, D-adonitol, D-arabitol, *m*-inositol, D-mannitol, D-sorbitol, D-gluconate, saccharate, *α*-glycerophosphate, isovalerate, nonanoate, adipate, pimelate, aconitate, L-threonine, L-valine and putrescine.

^bBrown diffusible pigment formed during L-tyrosine hydrolysis.

Data from Bowman et al. (1998b).

According to data of the carbohydrate analysis and NMR data, the antigenic PS of *P. nigrifaciens* IAM 3010^T contained two D-glucosamine, L-fucosamine, 6-deoxytalosamine (pneumosamine) and 3-deoxy-2-octulosonic acid (KDO) residues. The polysaccharide had the following structure:

where 6dTalpNAc is 2-acetamido-2,6-dideoxy-L-talopyranose (pneumosamine)

Antigenic PS of marine bacteria of *Pseudoalteromonas* are defined as either linear or branched glycosaminoglycans which contain rare and unusual *N*-acylamino- and acidic sugars such as: 3-*O*-[(R)-1-carboxyethyl]-D-glucose (glucolactylic acid; *P. nigrifaciens* KMM 156); 3,6-dideoxy-3-(4-hydroxybutyramido)-D-galactose and 2-acetamido-2-deoxy-L-guluronic acid (*P. nigrifaciens* KMM 158); di-*N*-acetyl-D-bacillosamine and 4-(*N*-acetyl-D-alanyl)amino-4,6-dideoxy-D-glucose; *P. nigrifaciens* KMM 155); and 2-acetamido-2,6-dideoxy-L-talose (*N*-acetyl-pneumosamine; *P. nigrifaciens* IAM 3010^T).

The O-specific PS of *Pseudoalteromonas elyakovii* KMM 162^T was studied in detail. The chain is a peripheral part of lipopolysaccharide (LPS) and may be released from the bacterial cell into the surrounding space at a distance of 10–12 nm. Usually, the O-antigen is a regular heteropolysaccharide, occurring in some cases as a homopolysaccharide, linear or branched, built up of oligosaccharide repeating units (from di- to hexasaccharide, less commonly from hepta- and even octasaccharide). Components of PSs may contain various monosaccharides and non-carbohydrate substitutes. The polysaccharide chain of LPS may be neutral or acidic, but as a rule, the concentration of a negative charge does not exceed one acidic group per three monosaccharide residues. The structure of O-specific PS from *P. elyakovii* 162^T was established on the basis of the carbohydrate analysis data, methylation study, and ¹³C-NMR-spectroscopy study. This PS contains D-glucose, D-galactose, and 2-

acetamido-2-deoxy-D-galactose residues in the ratio of 2:1:2. The structure of the O-specific PS is as follows:

However, capsular PS of this strain has a different sugar composition (R. P. Gorshkova and E. L. Nazarenko, personal communication).

The O-specific PS of *Pseudoalteromonas* sp. KMM 634 was found to contain D-glucuronic acid, 2,3-diacetamido-2,3-dideoxy-D-glucuronic acid, 2,3-diacetamido-2,3-dideoxy-D-mannuronoyl-L-alanine, and 2-acetamido-2,4,6-trideoxy-4-[(S)-3-hydroxybutyramido]-D-glucose (Komandrova et al., 2000).

A sulfated O-specific PS containing D-mannose, L-rhamnose, and the sulfate group was obtained by mild acid hydrolysis of lipopolysaccharide (S-form) of “*Pseudoalteromonas marinoglutinosa*” KMM 232. This is the first report of a sulfated O-specific polysaccharide from a Gram-negative bacterium (Komandrova et al., 1998). An O-specific PS was obtained by mild degradation of the lipopolysaccharide of the marine bacterium “*Alteromonas marinoglutinosa*” NCIMB 1770 and found to contain D-galactose, *N*-acetyl-D-glucosamine, and *N*-acetyl-D-mannosamine residues (Komandrova et al., 2001).

An acidic polysaccharide was obtained from the lipopolysaccharide of *Pseudoalteromonas distincta* KMM 638^T, isolated from a marine sponge, and found to contain D-glucuronic acid (D-GlcA), 2-acetamido-2-deoxy-D-galactose (D-GalNAc), 2-acetamido-2,6-dideoxy-D-glucose (D-QuipNAc), and two unusual acidic amino sugars: 2-acetamido-2-deoxy-D-galacturonic acid (D-GalNAcA) and 5-acetamido-3,5,7,9-tetradeoxy-7-formamido-L-glycero-L-mannonulosonic acid (Pse5Ac7Fo, a derivative of pseudaminic acid; Muldoon et al., 2001).

Thus, PSs of marine aerobic proteobacteria incorporate rare and unusual acidic and *N*-acylamino sugars as well as noncarbohydrate substitutes, and they differ by a structural diversification even among strains of the same species. These variations may be a reflection of different eukaryotic hosts (mollusks, sponges and ascidians) and different ecological niches.

Some *Alteromonas*-*Pseudoalteromonas*-like producers of exogenous polysaccharides (exoPSs) and the role of these extracellular polysaccharides in heavy metal binding (Vincent et al., 1994) and bacterial cell attachment have been reported (Holmström and Kjelleberg, 1999). “*Alteromonas macleodii* subsp. *fijiensis*”

(Raguenes et al., 1996), and “*A. infernus*” (Raguenes et al., 1997) produce acidic exoPSs. During periodical cultivation in a liquid medium with glucose (30 g/liter) cells of “*A. infernus*” from stationary phase excreted an unusual water-soluble exoPS, which contained glucose, galactose, galacturonic and glucuronic acids (Raguenes et al., 1997).

Fatty Acid and Phospholipid Composition

Fatty acid (FA) and phospholipid (PL) compositions are widely used in identification. Owing to the high metabolic similarity of marine aerobic heterotrophs, application of chemotaxonomy should be useful for rapid and accurate identification at least up to the genus level of environmental isolates.

Fatty acid composition of type strains and environmental isolates are available for members of *Pseudoalteromonas* (Table 14), *Alteromonas* and *Marinomonas* (Matsui et al., 1991; Svetashev et al., 1995; Ivanova et al., 2000c). Among 30 fatty acids with 11 to 19 carbon atoms detected in alteromonads and pseudoalteromonads and the 16 fatty acids found in marinomonads, acids C16:1 (n-7), C16:0, C17:1 (n-8), and C18:1 (n-7) were predominant, whereas C14:0, C15:0, C15:1 (n-8), and C17:0 were minor components. The absence of cyclopropanoic FA and hydroxy FA are characteristic features of all strains studied. *Marinomonas* species had the simplest FA composition with only three major components (C16:0, C16:1 [n-7], and C18:1 [n-7]), which generally accounted for more than 90% of the total fatty acids. Branched-chain fatty acids were not detected. Specifically, the amount of C18:1 (n-7) reached 44.4–52.8%. It should be noted that two strains of *Marinomonas*, *M. vaga* and *M. communis*, showed highly similar fatty acid profiles. *Marinomonas mediterranea* (Solano and Sanchez-Amat, 1999) showed differences in C16:0 and C18:1(n-7), while still showing the genus-specific fatty acid profile (Table 15).

Overall, PLs accounted for from 55% (mainly for pigmented species) to 85% of the lipid extracts. The thin layer chromatography (TLC) studies revealed that phosphatidyl ethanolamine (PE) and phosphatidyl glycerol (PG) were the major phospholipids of agar cultures of *Pseudoalteromonas*, *Alteromonas* and *Marinomonas*. The proportion of these PL components had a characteristic genus-specific pattern (Table 16). The amounts of PE ranged from 56.9 to 67.7% for *Alteromonas* spp., from 78.1 to 87% for *Pseudoalteromonas* spp., and from 60.7 to 68.8% for *Marinomonas* spp., while the amounts of PG ranged from 32.3 to 43.1%, from 13.0 to 21.9%, and from 31.2 to 35.1%, respectively. A

glycolipid was detected in all lipid extracts of agar cultures. Neither diphosphatidyl glycerol (DPG) nor glycophospholipids were found. Differences in the PL compositions of the same strains grown in liquid and on solid media have been detected (Frolova et al., 2000; Ivanova et al., 2000c).

Family Alteromonadaceae

Ivanova and Mikhailov proposed a new family, Alteromonadaceae, comprising *Alteromonas* and related genera (Ivanova and Mikhailov, 2001a). Phylogenetic analyses have shown that the genera of *Alteromonas*, *Pseudoalteromonas* and *Idiomarina* represent a distinct cluster within the γ -subclass of the class Proteobacteria with a 16S rDNA similarity level of 96.9%, which corresponds to 45 differences per 1462 sequenced nucleotides (Fig. 1). Phenotypic and genotypic characteristics of the genera of the family Alteromonadaceae are presented in Tables 15, 16 and 17. The genus *Glaciecola* described by Bowman et al. (1998c) is phylogenetically closely related to *Alteromonas macleodii* and could be regarded as a member of this family. Thus, the genera of *Alteromonas*, *Pseudoalteromonas*, *Glaciecola*, *Idiomarina* and *Colwellia* comprise a monophyletic evolutionary line at a 95–100% confidence level. The 16S rDNA similarity values obtained for these genera are 90% or higher. However, R. Christen and E. Ivanova propose to create several new families, including Pseudoalteromonadaceae (genus *Pseudoalteromonas*), Colwelliaceae (genera *Colwellia*, *Idiomarina* and *Thalassomonas*) and an emended Alteromonadaceae (genera *Alteromonas* and *Glaciecola*; R. Christen and E. Ivanova, in preparation).

Isolation, Cultivation, and Identification

Isolation

The isolation of *Alteromonas*, *Pseudoalteromonas*, *Idiomarina* and certain *Colwellia* species is based on common microbiological techniques for autochthonous marine, heterotrophic aerobic or facultatively anaerobic bacteria. See, e.g., ZoBell (1946).

Many techniques described in this chapter originate from investigations of Mikhael Doudoroff and coauthors (Stanier et al., 1966), Linda and Paul Baumann and coauthors (Baumann et al., 1971; Baumann et al., 1972; Baumann and Baumann, 1981), and from Michel Gauthier and Violette Breittmayer (Gauthier and Breittmayer, 1992).

Na ₂ SO ₄	4.06 g
CaCl ₂ · 6H ₂ O	2.25 g
KCl	0.69 g
NaHCO ₃	0.20 g
KBr	0.10 g
SrCl ₂ · 6H ₂ O	0.42 g
H ₃ BO ₃	0.027 g
Na ₂ SiO ₃ · 9H ₂ O	0.005 g
NaF	0.003 g
NH ₄ NO ₃	0.002 g
FePO ₄ · 4H ₂ O	0.001 g
Distilled water	1 liter

Adjust pH to 8.0

ASW Formula of MacLeod (1968)

NaCl	23.4 g
MgSO ₄ · 7H ₂ O	24.6 g
KCl	1.5 g
CaCl ₂	2.9 g
Distilled water	1 liter

While some strains grow better on ASW, containing trace compounds, others require natural seawater, especially water from the isolation source.

Basal Medium

(BM; Baumann and Baumann, 1981)

Tris-HCl (1 M, pH 7.5)	50 or 100 ml
NH ₄ Cl	1 g
K ₂ HPO ₄ · 7H ₂ O	0.075 g
FeSO ₄ · 7H ₂ O	0.028 g
Distilled water	1 liter
ASW (half strength)	1 liter

Carbon sources should be added at concentration of 0.2% before sterilization (1.2 atm, 121°C, 15 min). Thermostable substances should be added by filtration to the liquefied BM cooled to 40°C. BM can be toxic for some strains which are inhibited by Tris. For strains requiring additional growth factors, amino acids (1 mg/liter, sterilization by filtration) or small amounts of yeast extract (about 10 mg), tryptone or casein hydrolysate can be added to the BM or basal medium agar, BMA, which is prepared by adding 15-20 g (Baumann and Baumann, 1981; Gauthier and Breittmayer, 1992) or up to 40 g of agar-agar per 1 liter of distilled water (Gauthier and Breittmayer, 1992). Several complex media can be used (Gauthier and Breittmayer, 1992) including yeast extract broth (YEB; BM supplemented with yeast extract [5 g/liter]) and yeast extract agar (YEA; yeast extract supplemented with agar [15 g/liter]); tryptic soya broth prepared with ASW (TSBS and its equivalent, TSBS with agar [TSAS], 15 g/liter); brain heart infusion

broth with ASW (BHIS) and BHIAS (BHIS with agar, 15 g/liter); casitone broth prepared with ASW (CBS) and its solid equivalent CAS (CBS supplemented with agar, 15 g/liter).

Marine broth (MB) and marine agar (MA), formula 2216 according to ZoBell's preparation (ZoBell, 1941, 1946) have been found suitable. Medium 2216, differs very little in composition from the medium recommended by B. Fischer (Fischer, 1894), who used fish extract in seawater ("ecological" media in modern terminology) for the isolation of marine microorganisms and who noted that many bacteria found in the sea failed to grow unless the media were prepared with seawater.

2216 Medium

(ZoBell, 1946)

Seawater ("aged")	1000.0 ml
Bacto-peptone	5.0 g
Ferric phosphate	0.1 g
Bacto-agar	15.0 g

After sterilization at 120°C for 20 min, medium 2216 has a pH 7.5–7.6 when in equilibrium with atmospheric CO₂. Aged seawater is prepared by storing fresh seawater in glass bottles in the dark for a few weeks or longer; the water should be collected from places that are reasonably free of fresh water or terrigenous pollution.

Youshimizu and Kimura (1976) medium in modification (Mikhailov et al., 1988) can be used:

Modified Youshimizu-Kimura Medium

Peptone	5.0 g
Yeast extract	2.5 g
Glucose	1.0 g
K ₂ HPO ₄	0.2 g
MgSO ₄	0.05 g
Agar	20–40 g
Trace of iron salts	
Natural seawater	750 ml
Tap or distilled water	250 ml

After sterilization the pH is 7.5. A total of 25 g of NaCl (better, not chemically pure) per 1 liter of distilled water can be used instead of natural sea- and tap water. TSB (tryptic soya broth), BHIB (brain heart infusion broth), CB (casitone broth), MB (marine broth) and MA (marine agar) are commercially available through Difco Laboratories (Detroit, MI, United States).

Certain other media can be used for the isolation of species of γ -Proteobacteria covered in this chapter (Cultivation; Biotechnological Potential).

Isolation Procedures

SAMPLING PROCEDURES The samples (water, sediments, organs of animals, parts of plants, etc.) should be collected aseptically. Seawater (especially for quantitative counts of culturable bacteria) can be sampled at different depths in sterile glass flasks or other containers (some-

times called bathometers). Different bathometers and problems of sampling procedures have been described by several marine microbiologists (e.g., Issatschenko, 1914; ZoBell, 1946; Baumann and Baumann, 1981; Mishustina et al., 1985, and Austin, 1988). Some authors recommended the use of a Niskin bottles (General Oceanics, Miami, FL, United States) for sampling (e.g., Tsyban et al., 1990). Sediments should be collected by core sampling using shovels and corers or by divers when possible. Bacteria adsorbed on inert surfaces and surfaces of plant, animals or some others organisms (or their teguments) have been collected using sterile cotton-tipped applicator sticks. In many cases, desorption of bacteria adsorbed to particles from sediment or seawater, disintegration of bacterial aggregates, surfaces ([bio]films), and suspension of teguments is obtained by sonication (22 kHz, 0.4 A, ~2 min) in a flask cooled in an ice bath. These samples can be used for direct isolation.

DIRECT ISOLATION Seawater samples are spread directly or from dilutions on solid media. Seawater (1–500 ml) can also been filtered through >0.2 micrometer pore size nitrocellulose filters, which are then placed on Petri dishes containing YEA, MA, BMA or other media with 0.1–0.2% of carbon and energy source. The volume of seawater will depend on the water source, pore size and diameter of filters, and medium used for direct isolation. After incubation of 3–7 days at 25–30°C, colonies are picked and restreaked on the same media. Species described in this chapter will generally grow at room temperature 18–25°C (10–20°C for isolation of *Colwellia* species). *Alteromonas macleodii* can be frequently obtained by direct isolation on Petri dishes containing BMA with 0.2% of lactose (Baumann and Baumann, 1981). Sediment samples are spread directly or from dilutions (approximately 1 g of sediment in 10 ml of sterile ASW or natural seawater) on the same solid media, observed for bacterial colonies and purified as described above. Similar manipulations are used for bacteria isolation by applicators and by some other methods. Agar-decomposing strains can be isolated easily on BMA without addition of organic compounds. Some *Alteromonas* strains can be isolated by using low-nutrient media, the organic-nutrient concentration of which is comparable to that found in oligotrophic marine environments, for example LON medium (0.2 mg of carbon per liter (Maeda et al., 1999; Maeda et al., 2000)).

ENRICHMENT CULTURES *Pseudoalteromonas denitrificans* strains have been isolated from seawater samples preincubated aerobically at 10°C in the dark in nutrient medium containing

L-glutamine, L-arginine, ethylenediamine tetraacetate (EDTA), K_2HPO_4 , and $FeSO_4$. Subsamples of enrichment cultures were spread on medium with the following composition: 0.5 g of Bacto-peptone, 0.5 g of Bacto-tryptone, 0.5 g of yeast extract, 200 ml of tap water, and 800 ml of seawater.

The Petri plates are incubated at 10°C, and *P. denitrificans* strains isolated from the plates and identified by their specific coloration—red, purple or blue (the color of prodigiosin and its derivatives depend on pH, medium content and temperature; Enger et al., 1987). The capacity to enzymatically degrade “marine” polysaccharides can be used for enrichment cultures of the studied bacteria. For example, carrageenanolytic strains are isolated by enrichment cultures containing carrageenan or red macroalgae, containing this polysaccharide (Lukyanov et al., 1994). During incubations of heterotrophic marine picoplankton in bottles, some bacterial groups are conspicuously favored. Bacteria of the genus *Pseudoalteromonas* rapidly multiply in substrate-amended North Sea water, whereas the densities of *Oceanospirillum* change little only. Different growth responses to substrate gradients could thus affect the competition between marine bacteria and may help to explain community shifts observed during enrichments (Eilers et al., 2000; Pernthaler et al., 2001).

No methods have been described for rapid isolation of organisms covered in this chapter. Colonies of pigmented *Pseudoalteromonas* and *Colwellia* species can be selected from isolating plates on the basis of their specific color, e.g., red or reddish, purple, purple-black, blue, violet, yellow, lemon-yellow, orange, brown and brown-black, and dark-green.

Cultivation

Alteromonas, *Pseudoalteromonas*, *Idiomarina* and *Colwellia* species generally grow well on complex media in any type of container. Seawater or NaCl (sodium cations) are necessary for growth. The strains are psychrotrophic (but temperature-tolerant) or psychrophilic. Some cultures should be kept in the dark (Gauthier and Breittmayer, 1992). Good aeration is recommended, except for *P. tunicata*, *P. ulvae* and *Colwellia* species, which are facultatively anaerobic. Diverse media have been used for producers of enzymes and secondary biologically active metabolites (Mikhailov and Ivanova, 1994; Elyakov et al., 1996; Mikhailov et al., 1999).

Preservation

Long-term preservation of species of *Alteromonas*, *Pseudoalteromonas*, *Idiomarina* and *Colwellia* can be achieved by lyophilization or by

immersion in liquid nitrogen, or cryoconservation by using low-temperature refrigerators. Lyophilized cultures can be prepared according to Baumann and Baumann (1981). Fresh colonies grown on solid media (MA, YEA, BHIS, or BMA) are suspended in 0.5 or 1 ml of a solution (ASW, 1 liter; yeast extract, 5 g; peptone, 5 g; adjusted to pH 7.5 with NaOH) and transferred aseptically into glass ampoules, which are then rapidly submerged in liquid nitrogen (or acetone-dry ice mixture), placed under vacuum for 10–12 h, then sealed and stored at 4–5°C. Freeze-dried cultures can be reconstituted by suspending the dry powder in about 0.5 ml of YEB and streaking a portion of the liquid onto YEA, while the remainder is inoculated into a tube containing 4 ml of the same medium. Growth is observed after some days of incubation at suitable temperature. After lyophilization, the cells of most species remain viable after 5–7 years of storage at 4°C (Gauthier and Breittmayer, 1992). Lyophilization does not support cell viability of *P. aurantia*, *P. citrea*, *P. luteoviolacea* and *P. rubra*. For these species, immersion in liquid nitrogen must be used for long-term preservation. A fresh culture in MB can be used (24 h of incubation at 20–25°C) or a suspension of cells grown under these same conditions on MA in one-quarter-strength sterile ASW. These suspensions are supplemented with sterile glycerol (10%, v/v) and distributed into freezing tubes (0.5 ml per 2-ml tube), which are rapidly immersed in liquid nitrogen; under these conditions, viable cells of the species were recovered after several years of storage (Gauthier and Breittmayer, 1992). These four pigmented species produce autotoxic antibiotics and they rapidly lose their viability on all media. To conserve bench cultures, it is necessary to perform weekly transfers, sometimes even 3 days for strains with a high autotoxic activity (Gauthier and Breittmayer, 1992). Most species considered in this chapter can be maintained on MA slants at 18°C (or lower temperatures) and transferred monthly. Some isolates of *A. macleodii* and *P. haloplanktis* tend to acquire growth factor requirements (amino acids) after prolonged cultivation on MA (Baumann and Baumann, 1981). The storage of many strains in ASW or MB supplemented with 30% glycerol (v/v) at –80°C can be used.

Identification

The bacteria covered in this chapter have similar morphology, physiology, biochemistry, which facilitates their identification at the family level. Most methods used for phenotypical analysis and identification of marine bacteria have been described by Baumann and Baumann (1981) and by Gauthier and Breittmayer (1992).

Strains are regular, straight or curved rods, which neither form spores nor microcysts. Most strains are motile by means of a polar unsheathed flagellum. Some strains of *P. luteoviolacea* and *P. denitrificans* possess a sheathed polar flagellum (Novic and Tyler, 1985; Enger et al., 1987). *Pseudoalteromonas denitrificans* sometimes forms a tuft of two to three polar flagella. Lateral flagella were described for *P. distincta* (Romanenko et al., 1995a). *Pseudoalteromonas piscicida* possess peritrichous flagella (Bein, 1954). *Idiomarina zobellii* cells are fimbriated, while *I. abyssalis* cells are enclosed in a sheath-like structure (Ivanova et al., 2000b).

On solid complex media, colonies of most *Alteromonas*, *Pseudoalteromonas*, *Idiomarina*, *Colwellia* and *Glaciecola* species cannot be differentiated in that they are small, convex with more or less regular edges, translucent whitish and yellowish (*Alteromonas* and *Idiomarina*), colorless or colored (*Pseudoalteromonas*, *Colwellia* and *Glaciecola*). Some *P. luteoviolacea*, *P. citrea* and *P. nigrifaciens* strains produce a brown-black pigment (melanoids) on complex solid media. Colonies of pigmented *Pseudoalteromonas*, *Glaciecola* and *Colwellia* strains can be differentiated by color. *Pseudoalteromonas citrea* and *P. aurantia* produce yellow and orange noncarotenoid pigments. *Pseudoalteromonas luteoviolacea* produces intracellular violacein, and *P. denitrificans*, *P. rubra* and *P. bacteriolytica*, prodigiosin:

Violacein

Prodigiosin

(R₁, R₂, R₃ = H or alkyl)

The strain *Pseudoalteromonas maricaloris* KMM 636^T (Ivanova et al., 2002b), isolated

from marine sponge *Fascaplysinopsis reticulata*, produce yellow-orange chromopeptides, bro-

moalterochromides (T. A. Kuznetsova and H. Laatsch, personal communication):

Bromoalterochromides A and B

The main differentiating characteristics of species assigned to *Alteromonas* and related genera are shown in Tables 3, 5, 6, 9, 11, 13, 15, 16 and 17. Identification of isolates can be done by comparing their characteristics with those of type strains, compiled in Table 4.

All species need seawater for growth and have strict Na^+ requirement. Growth-supporting NaCl concentrations are 1–10% for *Alteromonas*, 1–12–15% for *Pseudoalteromonas*, 0.6–15% for *Idiomarina*, 1–6% for *Colwellia* and 1.5–5% for *Glaciecola*. The presence of Na^+ and K^+ are essential for the oxidation of exogenous substrates, including intermediates of the tricarboxylic acid, while the activities of the enzymes of this cycle are independent of these ions (MacLeod et al., 1958; MacLeod and Hori, 1960). Also, Na^+ ions play a role in the functioning of several permeation systems, Na-dependent transport systems of amino acids, maintenance of the integrity of the cell wall, and some other functions investigated by MacLeod and coworkers (Gauthier and Breittmayer, 1992).

Except for *P. tunicata* and *P. ulvae*, all species of the *Alteromonas*, *Pseudoalteromonas*, *Idiomarina* and *Glaciecola* genera are aerobic. *Colwellia* species, except *C. maris*, are facultatively anaerobic. All species of the genera *Alteromonas*, *Pseudoalteromonas* and *Idiomarina* are resistant to O/129 (except for *P. tunicata* and *P. ulvae*), and to lincomycin, but are sensitive to erythromycin.

Except for *P. denitrificans* and some strains of *P. haloplanktis*, none of the species produces nitrites from nitrates. None of species has a constitutive arginine dihydrolase system or accumulates polyhydroxybutyrate as intracellular storage product.

Alteromonas strains can grow between 10 and 35–40°C, *Pseudoalteromonas* strains from 4 to

35–40°C, *Idiomarina* strains from 4 to 35°C, *Colwellia* strains from 2 to 25°C, and *Glaciecola* species from –2 to 20–25°C.

The ability to oxidize or ferment D-glucose is an important diagnostic test. The phenol-red-containing Leifson's O/F medium adapted to marine bacteria gives reliable results (Leifson, 1963).

Alteromonas, *Pseudoalteromonas*, *Idiomarina*, *Colwellia* and *Glaciecola* species can use several organic compounds as sole source of carbon and energy, including carbohydrates, especially D-glucose and D-fructose (except for strains of *Idiomarina*, all *Glaciecola* strains and some *Pseudoalteromonas* species), alcohols, carboxylic acids, amino acids, and aromatic compounds. *Alteromonas macleodii*, *Pseudoalteromonas haloplanktis*, and *P. espejiana* use D-glucose and D-fructose through an inducible Entner-Doudoroff pathway. The API system (Analytab Products, Plainview, NY) and other commercial systems have been used to analyze the consumption of organic compounds as the sole or main carbon and energy source, and determine some other biochemical properties of bacteria.

The cellular fatty acid profile of the bacteria is a valuable taxonomic marker. Major fatty acids are: for *Alteromonas macleodii* and *Pseudoalteromonas*, 16:0 and 16:1 ω 7c; for *Idiomarina*, i15:0 and i17:0; for *Glaciecola*, 16:0, 16:1 ω 7c and 18:1 ω 7c; and for *Colwellia*, 22:6 ω 3 (Table 106).

Ecology of *Alteromonas* and Related Bacteria

The bacteria of this chapter are widely distributed obligate marine bacteria. Habitats and ecological niches of these microorganisms are

diverse (Austin, 1988; Fenical, 1993; Mikhailov and Ivanova, 1994; Mikhailov et al., 1999; Ivanova and Mikhailov, 2001a; Ivanova et al., 2001b). Sources of isolation and the geographic distribution of species of *Alteromonas*, *Glaciecola*, *Pseudoalteromonas*, *Colwellia*, *Idiomarina* and *Thalassomonas* are shown in Table 4. This group are common inhabitants of the coastal, open and deep waters of the seas and oceans (Pacific, Atlantic, Indian, Arctic and Antarctic). Members of *Alteromonas*-like bacteria are isolated from a variety of biotopes, i.e., the surface of biological and non-biological objects, sediments, seawater, intestines of marine animals, sea ice, etc. Bacteria of this group, with the exception of type strain *P. nigri-faciens*, have never been isolated from soil or other terrestrial biotopes because of their obligate requirement for Na⁺ (≥100 mM NaCl). Bacteria of these genera are heterotrophs, chemorganotrophs, psychrotrophs, slightly or moderately halophilic.

Because tentative identification of pigmented antibiotic-producing species of pseudoalteromonads is relatively simple, their distribution in the coastal waters of the Mediterranean Sea has been intensively studied. According to Gauthier et al. (1975) and Lemos et al. (1985), strains of *P. rubra*, *P. luteoviolacea*, *P. citrea* and *P. aurantia* are constantly isolated from seawater samples in autumn during phytoplankton blooms and represent more than 5% of the total culturable microorganisms. Pigmented *Pseudoalteromonas*-like bacteria that produced antibiotics and autotoxins were isolated from Australian (Gavrilovic et al., 1982) and Japanese (Ezura et al., 1988) coastal waters, from sediment samples, phyto- and zooplankton, and marine invertebrates of the Sea of Japan (Nair and Simidu, 1987; Ivanova et al., 1998b). Interestingly, prodigiosin-producing strains of *P. denitrificans* were isolated only from the samples of seawater collected 90–100 m from Norway's fiords and have never been found in other coastal waters and sediments (Enger et al., 1987).

Bacteria of the genus *Pseudoalteromonas* are well-known producers of numerous biologically active substances. Some of these activities have been exploited commercially (Biotechnological Potential). Synthesis of some secondary metabolites is controlled by bacterial attachment to certain substrates (surfaces) with defined physical and chemical properties (Ivanova et al., 1998c). It is ecologically important that these bacteria can also regulate the morphogenesis of marine invertebrates (Letz and Wagner, 1993) by inducing the larval settlement of the starfish *Acan-taster planci*, which is a predator of the Great Barrier Reef corals and larvae of some other animals (Johnson et al., 1991). It has also been

reported that these bacteria are pathogenic for invertebrate larvae (Colwell and Sparks, 1967) and algae *Laminaria japonica* (Sawabe et al., 1998b). Bdellovibrios are intracellular parasites of *Vibrio* spp. but not of *P. atlantica* (Sutton and Besabt, 1994).

Biotechnological Potential

Alteromonas and Related Bacteria as Producers of Enzymes

Recent investigations have demonstrated marine *Alteromonas*-like organisms are a rich source of enzymes of industrial potential such as proteinases, endoglucanases, glycosidases, chitinases, agarases, nucleases and tyrosinases. Producers of highly active and specific hydrolases including alkaline phosphatase (Fedosov et al., 1991), β-1,3-glucanase (laminaranase; Sova et al., 1994), polyuridyl-endoribonuclease (Romanenko et al., 1995b), RNases (Ivanova et al., 1994b; Plisova et al., 1996), α-*N*-acetylglactosaminidase (Bakunina et al., 1994), α-galactosidase (Bakunina et al., 1996), β-*N*-acetylglucosaminidases (Ivanova et al., 1998a) have been described. *Pseudoalteromonas* strains were found to synthesize restrictases (Dedkov et al., 1990), nucleoside-kinases (Terent'ev et al., 1998), amylase (Gavrilovic et al., 1982; Aghajari et al., 1998), phospholipase and lipophospholipase (Cadman and Eichberg, 1983) and other enzymes (Ivanova and Mikhailov, 1992a; Mikhailov and Ivanova, 1994).

Many bacteria from the sea (ZoBell and Rittenberg, 1938; Gooday, 1990; Gooday, 1994), including *Alteromonas*-*Pseudoalteromonas*, are able to produce chitinolytic enzymes, chitinases and β-*N*-acetylglucosaminidases (chitobias). The search for bacterial producers of chitinases resulted in the isolation from the bottom deposit sample (depth 5 m) of the Sagami Bay, Japan, of *Alteromonas* strain O-7, which possesses a highly active extracellular chitinase Chi-A (Tsujiibo et al., 1991). The amino acid sequences of this chitinase was homologous to described chitinases from terrestrial bacteria such as *Serratia marcescens* and *Bacillus circulans*. However, chitinase ChiA showed higher activity and stability in seawater owing to the presence of sodium, potassium, calcium and magnesium ions (Tsujiibo et al., 1992). Subsequent investigations revealed that chitinolytic system of the strain O-7 included three chitinases (ChiA, ChiB, and ChiC) and three *N*-acetylglucosaminidases (Tsujiibo et al., 1993; Tsujiibo et al., 1995; Tsujiibo et al., 1998). The cluster of three closely linked chitinase genes organized in the order *chiA*, *chiB* and *chiC*, with the same transcriptional direction, and two unlinked genes, *chiP* and *chiQ*, involved

in chitin degradation in *Pseudoalteromonas* sp. S91, were cloned, sequenced and characterized. The deduced amino acid sequences revealed that ChiA, ChiB and ChiC exhibited similarities to chitinases belonging to family 18 of the glycosyl hydrolases, while ChiP and ChiQ belonged to family 20 (Techkarnjanaruk et al., 1997; Techkarnjanaruk and Goodman, 1999). Reports reveal that only a restricted number of alteromonad and pseudoalteromonad strains possess chitinases (Ivanova and Mikhailov, 1992a; Ivanova et al., 1992b).

Polysaccharide agar-agar (also known as agar, which is a mixture of agarose and agaropectin) is available in red algae cell walls. Agar can be degraded by both marine and other bacteria using two pathways which differ in the specificity of the cleaving enzymes. The first pathway is based on an extracellular β -agarases (Morris et al., 1983a; Morris et al., 1983b). Endo β -agarase I cleaves the β -(1,4) linkages of large agar polymers to a mixture of oligosaccharides with neoagarotetraose as a main and final product. Oligosaccharides are then hydrolyzed by the cell-bound exo β -agarase II, yielding neoagarobiose. Neoagarobiose is hydrolyzed intracellularly to 3,6-anhydro-L-galactose and galactose by neoagarobiose hydrolase (Day and Yaphe, 1975). The second pathway involves the cleavage of α -(1,3) linkages of agarose by extracellular α -agarases (Potin et al., 1991; Potin et al., 1993), yielding oligosaccharides from the agarobiose series, which contain D-galactose at the non-reducing end (Vera et al., 1998). *Pseudoalteromonas atlantica* strains are an industrial source of agarases (Yaphe, 1957; Akagawa-Matsushita et al., 1992b). An extracellular agarase was isolated from *Alteromonas* sp. C-1 (Leon et al., 1992) characterized by the molecular mass (m.m.) of 52 kDa, optimum pH 6.5, sensitivity to NaCl, and hydrolysis of agar with neoagarotetraose as a main product. Among pseudoalteromonads, producers of β -agarases have been characterized (Romanenko et al., 1994a; Romanenko et al., 1994b, 1994c). The enzyme from *Pseudoalteromonas antarctica* N-1 hydrolyzed β -1,4-glycosidic linkages of agar, yielding neoagarotetraose and neoagarohexaose as main products, and exhibited maximal activity at pH 7 (Vera et al., 1998).

α -D-Galactosidase cleaves the α -D-galactopyranosyl residue from the nonreducing end of various oligosaccharides, branched polysaccharides (galactans and galactomannans), as well as corresponding glycosides and various natural glycoconjugates. Marine bacteria, including *Alteromonas*-like strains, have been screened for α -galactosidases, α -N-acetylglactosaminidases, and β -N-acetylglucosaminidases (Bakunina et al., 1994; Bakunina et al., 1996; Ivanova et al.,

1998a). α -Galactosidase and agarase were isolated and partially purified from the agarolytic strain of *Pseudoalteromonas citrea* KMM 188 associated with a mussel. Enzymes were characterized by a pH optimum of 6.0–7.5 and temperature stability of up to 30°C (Bakunina et al., 1996). *Pseudoalteromonas* sp. KMM 701 was found to produce α -galactosidase capable of inactivating the group specificity of B erythrocytes (group III) of human blood and of A erythrocytes (group II). The enzyme was stable at 20°C for 24 h at high NaCl concentrations, and had a pH optimum between 6.7 and 7.7. The enzyme was 4-fold more efficient than the α -galactosidase from green coffee beans. The molecular mass of the enzyme was 195 ± 5 kDa. The α -galactosidase was denatured by urea and guanidine hydrochloride. A sulfhydryl was essential for its catalytic activity, which did not depend on the presence of metal ions (Bakunina et al., 1998).

The cold-adapted β -galactosidase from *Pseudoalteromonas haloplanktis* TAE 79 was purified to homogeneity. The enzyme shared structural properties with *Escherichia coli* β -galactosidase (comparable subunit mass, 51% amino sequence identity, conservation of amino acid residues involved in catalysis, similar optimal pH value, and requirement for divalent metal ions) but was characterized by a higher catalytic efficiency on synthetic and natural substrates, a shift of apparent optimum activity toward low temperatures, and lower thermal stability. Assays of lactose hydrolysis in milk demonstrated that *P. haloplanktis* β -galactosidase can outperform the current commercial β -galactosidase from *Kluyveromyces marxianus* var. *lactis*, suggesting that the cold-adapted β -galactosidase could be used to hydrolyze lactose in dairy products processed in refrigerated equipment (Hoyoux et al., 2001). Psychrophilic enzymes produced by cold-adapted microorganisms display a high catalytic efficiency associated with high thermosensitivity. The application of cold-adapted enzymes offers considerable potential to the biotechnology industry (e.g., in the detergent and food industries), for the production of fine chemicals and bioremediation processes (Gerday et al., 2000).

Pseudoalteromonas carrageenovora is producer of carrageenases which decompose carrageenans, complex polysaccharides contained in the cell walls of *Rhodophyta algae* (Yaphe and Baxter, 1955; Yaphe, 1957; Yaphe, 1962). *Pseudoalteromonas carrageenovora* and 10% of *P. atlantica* strains are able to hydrolyze carrageenans as well as alginates (Akagawa-Matsushita et al., 1992b).

Pseudoalteromonas strains from the brown algae *Fucus evanescens*, *Chorda filum*, and the

sea cucumber *Sticopus* (*Apostichopus*) *japonicus* produce fucoidanases (fucoidan-hydrolases), which hydrolyze fucoidan, a polysaccharide of brown algae (Bakunina et al., 2000).

A laminaran-induced β -1,3-glucanase (laminaranase) with m.m. 40 kDa, temperature optimum 45°C, and pH optimum 5.5 was isolated from the type strain KMM 162 of *Pseudoalteromonas elyakovii*. Hydrolysis products of laminaran were laminaran oligosaccharides and glucose. The enzyme had transglycosylating activity and was endo-specific. Chemical modification indicated that tryptophan, histidine, and dicarboxylic acid residues were important for enzymatic activity (Sova et al., 1994).

Some bacterial strains are capable of expressing alginate lyase. Alginate is a linear polymer consisting of β -D-mannuronic and α -L-guluronic acid residues and is a part of the cell walls of brown algae. Strain H-4 of *Alteromonas* sp. produced extra- and intracellular alginolytic enzymes and utilized alginate as the sole source of carbon. Extracellular alginate lyase of strain H-4 was found to be a novel enzyme with a wide substrate specificity, m.m. of 32 kDa and an optimum pH of 7.5. The enzyme was unstable at temperatures above 30°C and in acidic media. Its activity increased in the presence of magnesium, sodium, and potassium ions (Sawabe et al., 1997; Sawabe et al., 1998b). Detailed taxonomic investigation of these alginolytic bacteria isolated from spot-wounded fronds of *Laminaria japonica* allowed them to be assigned to *Pseudoalteromonas elyakovii* (formerly *Alteromonas elyakovii*; Ivanova et al., 1996b; Sawabe et al., 2000).

Nucleic acids are widespread compounds in the sea environment as described by the presence of a large number of bacteria producing DNAses and RNAses, including proteobacteria (Wei et al., 1983; Przykorska et al., 1988; Austin, 1988; Romanenko and Mikhailov, 1992; Ivanova et al., 1994b; Plisova et al., 1996). Strain KMM 223, producer of polyuridyldonoribonuclease, exhibits a unique polyuridylic acid-hydrolyzing activity. This enzyme specifically degraded poly(U) by an endonuclease mechanism that results in oligonucleotides with terminal 5'-phosphate (Romanenko et al., 1995b; Plisova et al., 1996).

Some *Pseudoalteromonas haloplanktis* strains produce isoschizomeric endonucleases of the known restrictases *Sau961* and *KpnI* (Dedkov et al., 1990). Isoschizomers of endonucleases *XbaI*, *EcoRII*, *BalI*, *NaeI* have also been found in *Pseudoalteromonas* strains (Romanenko et al., 2001).

An alkaline phosphatase (AP) has been characterized from strain KMM 162 of *Pseudoalteromonas elyakovii* that was isolated from the

coelomic liquid of the mussel *Crenomytilus grayanus*. The AP from the strain KMM 162 had an activity of 7000 units/mg of protein at pH 7.5–11.0. The activity of the enzyme depended on concentration of ions in the test assay. Replacement of glucose with laminaran (β -1,3-glucan) in culture medium resulted in the synthesis of both AP and laminaranase with high activities (Fedosov et al., 1991; Ivanova et al., 1991). Other AP-producing *Alteromonas*-like proteobacteria have been described (Ivanova et al., 1992c; Terent'ev et al., 1994).

Alteromonas and *Pseudoalteromonas* strains synthesize highly active proteolytic enzymes (Austin, 1988; Ivanova and Mikhailov, 1992a; Ivanova et al., 1992d). A serine-protease (Dohmoto and Miyachi, 1991) has been reported to occur in a strain isolated from the mussel *Mytilus edulis*. The proteinase showed high degrading activity of mussel thread (byssus). *Pseudoalteromonas peptidolytica* (Venkateswaran and Dohmoto, 2000) has been described as a new proteinase-producing bacterium.

A strain of *P. piscicida*, isolated from an algae of the Black Sea, displayed thrombolytic activity. This strain excreted an exoprotease, the lyophilized enzyme (1 mg/ml) of which lysed thrombs (clots) of human blood in vitro after 5 min of incubation. After the incubation, the activity was completely depressed (Demina et al., 1990). The enzyme showed direct fibrinolytic activity since plasminogen was not activated.

Alteromonas haloplanktis strain S5B produced an aminopeptidase and an extracellular trypsin-like protease. The latter represented an alkaline protease, the activity of which increased with calcium ions. The specific properties of the isolated enzyme were thermal lability and activity at low temperatures. These features play an important role in the destruction of fish proteins in the sea environment (Odagami et al., 1994).

Bacteria covered in this chapter also produce oxidoreductases. Tyrosinases can exhibit two enzymatic activities, namely cresolase and catecholase, which catalyze the conversion of tyrosine via L-3,4-dihydroxyphenylalanine (L-DOPA) to melanin. L-DOPA is known an effective agent in the treatment of Parkinson's and some other diseases. Model experiments have revealed the involvement of tyrosinases from marine bacteria in the metamorphosis and adhesions of oyster larvae of *Crassostrea virginica* and other invertebrates (Bonar et al., 1986). Screening of *Pseudoalteromonas* strains, both associated with invertebrates and free living, has shown a great number of strains (up to 40%) that express high level of tyrosinase activity. Melanogenic pseudoalteromonads represented by *P. citrea* and *P. distincta* were characterized by a high intracellular general and

specific tyrosinase activities. β -Tyrosinase with the m.m. of 26.3 kDa was isolated from cells of *P. distincta* KMM 638^T (Romanenko et al., 1994c).

Secondary Metabolites of Pseudoalteromonads and Related Bacteria

Microorganisms of the marine environment are capable of synthesizing diverse bioactive secondary metabolites. De Giaxa (1889) was the first to report on marine bacteria with properties antagonistic to the causal agents of anthrax and cholera. Later, ZoBell and his coworkers (ZoBell and Upham, 1944; ZoBell and Upham, 1946; Rosenfeld and ZoBell, 1947), and other researchers (Baam et al., 1966a; Baam et al., 1966b; Baslow, 1969) based their studies on these earlier findings.

The first report on the antibiotic activity of *Alteromonas*-like bacteria revealed the ability of a certain "variant" of *Pseudomonas piscicida* to inhibit the growth of yeast (Buck and Meyers, 1966). In 1966, Burkholder et al. (1966) reported about the isolation of the brominated pyrrole antibiotic (2,3,4-tribromo-5[1'-hydroxy-2',4'-dibromophenyl]-pyrrol) from "*Pseudomonas bromoutilis*." This unique compound, consisting of more than 70% bromine (Lowell, 1966), was found later in *P. luteoviolacea* and named "pentabromopseudilin" (Laatsch and Pudleiner, 1989; Hanefeld et al., 1994). Pentabromopseudilin was active against Gram-positive test cultures in low concentrations. It was the first antibiotic from an obligately marine bacterium for which a novel chemical structure was reported. Two strains of "*P. bromoutilis*" were isolated from turtle grass *Thalassia* sp. collected in tropical waters near Puerto Rico. "*Pseudomonas bromoutilis*" had a respiratory type of metabolism, were catalase negative, and formed yellow colonies with a dark trace on solid media. Subsequent biochemical characteristics indicated that these strains belonged to either *Alteromonas* or *Pseudoalteromonas*.

Pentabromopseudilin

In 1974, Anderson isolated from a seawater sample (obtained from the northern area of the Pacific Ocean) a purple-colored bacterium resembling the known *Chromobacterium marinum* (Anderson et al., 1974). The phenotypic characteristics of the isolate were similar to those of the genera *Alteromonas* or *Pseudoalteromonas*. This strain synthesized several antimicrobial compounds, which were extracted from the cells by ethyl acetate: tetrabromopyrrol, hexabrom-2,2'-bipyrrol and 2-(2'-hydroxy-3',5'-dibromophenyl)-3,4,5-tribromopyrrol. Tetrabromopyrrol, the most active of the compounds, inhibited the growth of *Escherichia coli*, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Candida albicans* (Wratten et al., 1977).

A collection of violet-pigmented strains of *Pseudoalteromonas* (*Alteromonas*) *luteoviolacea* was studied by Gauthier and Flatau (1976c). They isolated two brominated compounds together with polyanionic weakly cell-bound polysaccharides, which diffused into the medium. The substances inhibited the growth of Gram-positive microorganisms, such as *Bacillus firmus*, *Staphylococcus epidermidis*, and *Staphylococcus aureus*, but were less active against Gram-negative bacteria, e.g., *Morganella morganii* and *Shigella dysenteriae*. Some other pigmented species of *Pseudoalteromonas* genus, *P. rubra*, *P. citrea* and *P. aurantia*, were also able to synthesize autotoxic high molecular weight antibiotic substances, active against Gram-positive and Gram-negative microorganisms (Gauthier, 1976a; Gauthier, 1976b; Gauthier, 1977; Ballester et al., 1977; Gauthier and Breittmayer, 1979). Three metabolites active against protist *Paramecium caudatum* were later isolated from *Pseudoalteromonas* (*Alteromonas*) *luteoviolacea* (Kamei et al., 1986).

Members of Fenical's group from Scripps Institution of Oceanography have noticed that shrimps (*Palaemon macrodactylus*) that usually dwell in estuaries were resistant to pathogens, including the known pathogen of the crustacean *Lagenidium callinectes*. Shrimp eggs are colonized by bacterial cells that probably protect eggs by producing antibiotic substances. The associative bacteria were isolated in axenic culture and identified as *Alteromonas* sp. During laboratory cultivation, *Alteromonas* sp. synthesized the fungicidal agent 2,3-indolinedione known also as "isatin." Removal of epibiotic alteromonads led to the death of shrimp embryos in contrast to embryos reinoculated with *Alteromonas* or treated by isatin (Gil-Turnes et al., 1989). Isatin is used for synthesis of indigoid dyes and its derivatives as fungicides, herbicides and other preparations.

2,3-Indolinedion (isatin)

Also, Fenical and collaborators showed that an unidentified Gram-negative bacterium, probably a pseudoalteromonad that coated eggs of the lobster *Homarus americanus*, was able to synthesize a large amount of 2-*p*-hydroxyphenylethanol (tyrosol), which inhibited the growth of *L. callinectes* (Gil-Turnes and Fenical, 1992). Earlier, tyrosol was determined to be a metabolite of terrestrial microscopic fungi.

2-*p*-Hydroxyphenylethanol (tyrosol)

Bacteria of *Alteromonas* genus were found to influence some species of red microalgae (during “blooming”) or red tide plankton. *Alteromonas* sp. 9066-46 was isolated from coastal seawater of the Sea of Japan and displayed an inhibitory effect on the growth of the red algae *Gymnodium nagasakiense*. When cell suspensions of strain 9066-46 from the early and late logarithmic phases were added to the microalgae culture, growth of the algae was considerably decreased. The same specific algicidal activity was obtained with ethylacetate extracts of *Alteromonas* sp. 9066-46. Algicidal effects against other microalgae species were not found (Sugahara et al., 1992).

The bacterium *Alteromonas* sp., synthesizing tetracyclic alkaloid alteramide, was isolated from the sponge *Halichondria okadai* found in the Sea

of Japan (Shigemori et al., 1992). Alteramide is a representative of the new class of macrocyclic lactams, which undergoes an intramolecular photochemical cyclization with the formation of a hexacyclic product. Alteramide showed a cytotoxic activity against leukemia P-388, lymphoma L 1210 and epidermal carcinoma KB cells in vitro at the concentration of 0.1, 1.7 and 5.0 µg/ml, respectively. The cyclization product had no cytotoxic activity

Alteramide

Isolated from the seawater bacterium “*Alteromonas rava*” SANK 73390 (Kodama et al., 1993), a new antibiotic thiomarinol (Shiozawa et al., 1993; Shiozawa and Takahashi, 1994) was described. Thiomarinol is a derivative of two types of antibiotics, pseudomonic acid and pyrroline antibiotics, containing a disulfide bridge. Activity of thiomarinol against Gram-positive bacteria, including antibiotic-tolerant *Staphylococcus aureus* strains and Gram-negative bacteria, was considerably higher than those of pseudomonic acid and acylpyrrolitin. Later, thiomarinol was renamed “thiomarinol A” (Shiozawa et al., 1995) when thiomarinols B and C were described. Thiomarinol B has the greatest antimicrobial activity among the thiomarinols, whereas C is less active than A. The minimum inhibitory concentration of thiomarinol B towards *S. aureus* 535 (MRSA) was <0.01 µg/ml. It should be noted that thiomarinol A had been isolated earlier from *Alteromonas* sp., as one of the two new derivatives of pseudomonic acid (Stierle and Stierle, 1992), but the absolute configuration of this compound was not determined. Thiomarinols D, E, F and G were described later (Shiozawa et al., 1997).

Thiomarinol A (R = OH); Thiomarinol C (R = H)

Thiomarinol B

Several research groups reported that known metabolites (such as tetrodotoxin, saxitoxin, eicosapentaenoic acid, tetrabromodiphenyl ethers, etc.) are really synthesized by symbiotic bacteria but not by their hosts (such as marine fish, mollusks and other animals; Noguchi et al., 1986; Yasumoto et al., 1986; Yazawa et al., 1988; Kodama et al., 1989; Elyakov et al., 1991). Tetrodotoxin is one of the strongest natural neurotoxins. It has valuable pharmacological properties as an analgesic, e.g., an agent against asthma, arthritis, impotence and other diseases. The assumption that tetrodotoxin is synthesized by symbiotic microorganisms was confirmed by toxin production of *Pseudomonas*, *Vibrio* and other Gram-negative bacteria isolated from sea animals (Noguchi et al., 1986; Yasumoto et al., 1986). The new species *Alteromonas tetraodonis*, isolated from skin slime of Fugu fish, was described by Simidu and collaborators (Simidu et al., 1990). It was also demonstrated that tetrodotoxin was synthesized by free-living, both sea and fresh water Gram-negative and Gram-positive bacteria (Simidu et al., 1995). The ability to produce tetrodotoxin by bacteria, however, is currently under discussion (Matsumura, 2001; Kim and Kim, 2001).

Tetrodotoxin

By screening 3000 bacterial strains from coastal waters of Japan, producers of enzyme inhibitors have been found. *Alteromonas* sp. B-10-31 produced low molecular weight (1.5–1.7 kDa) peptides called “marinostatins,” which act as an inhibitor of proteases (subtilisin). Three categories of marinostatins were isolated: A, B (B-1 and B-2) and C (C-1 and C-2). The main components were marinostatins B and C,

containing alanine, arginine, aspartic and glutamic acids, methionine, phenylalanine, proline, serine, threonine and tyrosine. Marinostatins were stable at pH 2–6, specific to serine proteases such as subtilisin, bull α -chymotrypsin, pancreatic protease, proteinase K, and inhibited by ions of Co^{2+} and Fe^{2+} . High molecular inhibitors named “monostatins” were also isolated from strain B-10-31. Monostatins are glycoproteins (about 20 kDa), stable at pH 2–12 and specific to thiol proteases. Monostatins are inhibited by ions of Cu^{2+} , Fe^{2+} and Fe^{3+} (Imada et al., 1985a; Imada et al., 1985b; Imada et al., 1985c; Imada et al., 1986a; Imada et al., 1986b).

Leupeptins A, B and C from *Alteromonas* sp. are thiolproteinase inhibitors (Hamato et al., 1984). These possess at the C-terminus an aldehyde of arginine, followed by amino acids acetyl-leucine and valine, acetyl-leucine and isoleucine, acetyl-leucine and leucine for leupeptins A, B and C, respectively. Similar aldehyde-containing peptides were isolated earlier only from various species of actinomycetes (actinobacteria).

Scientists of the Roche Research Institute (Australia) isolated from seawater a strain of *Pseudoalteromonas* (*Alteromonas*) *rubra*, which in liquid culture synthesized a series of unusual C_{16} aromatic acids. These compounds had myorelaxant properties (Holland et al., 1984).

 C_{16} aromatic acids of *Pseudoalteromonas rubra*

Isoprenoid quinones, and in particular, ubiquinones (coenzymes Q) are components of the respiratory chain where they participate in the transport of electrons and participate in oxidative phosphorylation. The biological activity of quinones allows them to be used as antioxidants in anemia, muscular dystrophy, and cardiovascular insufficiency. Numerous strains of terrestrial pseudomonads have been pro-

posed as sources of ubiquinones. However, also marine bacteria such as *Alteromonas* and *Marinomonas* containing ubiquinones Q₈, *Deleya* (*Halomonas*) and marine *Pseudomonas* spp. containing Q₉, *Shewanella* spp. containing ubiquinones and menaquinones, and *S. putrefaciens* containing methylmenaquinones (Akagawa-Matsushita et al., 1992a) could be used as sources of ubiquinones.

Ubiquinones

Alteromonas sp. KK 10304, associated with the marine sponge *Halichondria okadai*, effectively inhibited settling of the cyprids of the barnacle, *Balanus amphitrite*. Bioassay-guided isolation indicated ubiquinone-8 as an effective inhibitor of cyprid settling (Kon-ya et al., 1995).

From the surface of the cyanobacterium *Microcoleus lyngbyaceus* (from waters off the coast of Puerto Rico) four pseudoalteromonad-like bacteria (one violet, one red, and two yellow) were isolated. All of them synthesized the same quinone (20 mg/liter of medium) with a strong fungicidal activity (Fenical, 1993).

Quinone is synthesized by associated bacteria of *M. lyngbyaceus*

Several reports indicate the production of siderophores by marine bacteria. The first described structure was bisucaberin, isolated from *Pseudoalteromonas* (*Alteromonas*) *haloplanktis* SB-1123 (Kameyama et al., 1987; Takahashi et al., 1987). The strain was isolated from sediments (at a depth of 3300 m) obtained off the coast of the Japanese prefecture of Aomori and in less than 2 days cultivation at 27°C on medium containing fishmeal and maltose. Under these conditions, the strain synthesized 700 mg of bisucaberin per liter of medium. This siderophore has the unique biological property to make tumor cells sensitive to the cytolytic effect of macrophages. The cytotoxic effect of bisucaberin was demonstrated on tumor cells of fibrosarcoma 1023 (Kameyama et al., 1987).

Bisucaberin

Extraordinary affinity for iron is displayed by the alterobactins A and B isolated from *Pseudoalteromonas* (*Alteromonas*) *luteoviolacea*. These cyclic depsipeptides contain two unusual amino acids—L-treo-β-hydroxyaspartic and (3R, 4S)-4,8-diamino-3-hydroxyoctanoic acids. Alterobactin has been chemically synthesized (Deng et al., 1995).

Alterobactin A

Nonmedical: *Pseudomonas*

EDWARD R. B. MOORE, BRIAN J. TINDALL, VITOR A. P. MARTINS DOS SANTOS,
DIETMAR H. PIEPER, JUAN-LUIS RAMOS AND NORBERTO J. PALLERONI

Introduction

Pseudomonas comprises a genus of species capable of utilizing a wide range of organic and inorganic compounds and of living under diverse environmental conditions. Consequently, they are ubiquitous in soil and water ecosystems and are important as plant, animal and human pathogens (Palleroni, 1992; Schroth et al., 1992). The genus *Pseudomonas* is well known for its metabolic versatility and genetic plasticity. The species of *Pseudomonas*, in general, grow rapidly and are particularly renowned for their ability to metabolize an extensive number of substrates, including toxic organic chemicals, such as aliphatic and aromatic hydrocarbons. Strains of *Pseudomonas* species are often resistant to antibiotics, disinfectants, detergents, heavy metals, and organic solvents. Some strains have been confirmed to produce metabolites that stimulate plant growth or inhibit plant pests.

Pseudomonas was already recognized as a complex collection of a large number of described species when the previous two editions of *The Prokaryotes* (Bergey, 1981; Schroth et al., 1981; Schroth et al., 1992; Stolp and Gadkari, 1981; Palleroni, 1992) were published. The heterogeneity of *Pseudomonas* has been well documented from comprehensive studies dating to more than 40 years ago. For example, the detailed survey by Stanier et al. (1966) of 267 strains of aerobic pseudomonads clearly exposed the catabolic diversity of the species comprising the genus and provided insight into the phylogenetic diversity that would become more apparent a few years later. Much of what can be written today about *Pseudomonas*, particularly related to the phenotypic, as well as metabolic characteristics, has already been described in detail by several different groups (Clark and Ornston, 1975; Clark and Richmond, 1975; Palleroni, 1975).

Wherever possible, the focus of this compilation on nonmedical aspects of the genus *Pseudomonas* is directed at information that has come to light since the last edition of *The*

Prokaryotes in 1992. Much of microbial systematics has “evolved” in new directions within the last decade as a result of being able to access the phylogenetic relationships of microbial taxa. Elucidation of the “natural” relationships of bacteria has had a profound impact on the systematic reorganization of bacteria, in general, and on *Pseudomonas*, in particular. Many of the species that were described previously as *Pseudomonas* have been reclassified within new genera, and recognition of the phylogenetic heterogeneity of bacteria classified as *Pseudomonas* has initiated re-evaluations of the phenotypic characteristics, metabolic activities, genetics, ecology and other characteristics, in light of the inter- and intrageneric phylogenetic relationships. The early studies on the phylogenetic analyses of *Pseudomonas*, in fact, helped develop much of the methodology and technique that would be applied to the analyses of other prokaryotes in the years to come. Recently, advances in molecular biology, genome sequencing (the genomes of four species of *Pseudomonas* have been determined at the time of this writing), genomics and proteomics have presented a wealth of data for “pseudomonadologists” to access in trying to understand all facets of these bacteria. Researchers have only recently started to scale the mountain of information available.

Phylogeny

The phylogenetic heterogeneity of pseudomonads was recognized initially from work on the comparative biochemistry of the bacteria (Stanier, 1968), which established the groundwork upon which much of the later work was based. The ability to further differentiate *Pseudomonas* (sensu stricto) from phenotypically similar bacteria has been due, primarily, to the development and application of methods for analyzing bacteria at the molecular level. Palleroni and colleagues at the University of California at Berkeley (Palleroni et al., 1973) were able to discern distinct intrageneric

groupings among, what were, at that time, the species comprising the genus *Pseudomonas*, by the use of rRNA similarities. The group of De Ley, at the Universiteit Gent in Belgium, also applied the use of rRNA-DNA hybridization to an extensive number of studies on the pseudomonads. De Vos et al. (1989) proposed, and it is now generally accepted, that the genus *Pseudomonas* is limited to the species related to *P. aeruginosa* in the DNA-rRNA homology group I (Palleroni et al., 1973), within the γ -subclass of the Proteobacteria (Woese et al., 1985), currently reorganized as the class "Gammaproteobacteria" (Krieg and Garrity, 2001). The species comprising this grouping have been referred to as the "true *Pseudomonas*" or the "fluorescent pseudomonads" because of the notable fluorescent, water-soluble pigments produced by *P. aeruginosa*, *P. fluorescens* and some other well-known species of the genus. Nevertheless, to add yet another note of confusion to the complexity of *Pseudomonas*, not all species of the so-called "fluorescent pseudomonads" actually produce fluorescent pigments, e.g., *P. alcaligenes*, *P. mendocina*, *P. stutzeri*, to name but a few. To differentiate systematically *Pseudomonas* (sensu stricto) from other bacteria that were included previously in the genus or those that are newly isolated and characterized, analyses of ribosomal RNA (rRNA) similarities have proven applicable for inferring definitive systematic relationships to the genus level (in most cases) and to subgenus levels (in some cases).

The rRNA sequence similarities between *Pseudomonas* species were determined initially by hybridization of DNA to ribosomal rRNA, in the group of Roger Stanier at the University of California at Berkeley (Palleroni, et al., 1973). The hybridization methodology revealed internal subdivisions of five distinct rRNA "homology groups" that corresponded to the levels of differentiation observed between different genera or families. The observed subdivisions of *Pseudomonas* were confirmed repeatedly by various methodologies performed throughout the following years in many other laboratories (Byng et al., 1983; De Vos and De Ley, 1983; Oyaizu and Komagata, 1983; De Vos et al., 1985; De Vos et al., 1989; Stead, 1992).

Subsequent to the analyses using the DNA-rRNA hybridization methods, another approach targeting rRNAs was applied to the analysis of *Pseudomonas* in the laboratory of Carl Woese at the University of Illinois. Utilizing a protocol of sequence determination and profiling of rRNA oligonucleotides to produce taxa-specific "catalogues" (Fox et al., 1980), Woese et al. (1984) described the diversity of the pseudomonads along the same divisions that had been recognized previously by the Berkeley group.

Essentially, some species that were classified as members of the genus *Pseudomonas* were observed to be less similar phylogenetically to other pseudomonads than they were to non-pseudomonad bacteria, e.g., enterics, phototrophs, nitrogen-fixing plant symbionts, etc. With such approaches, the "natural" system of bacterial classification that had been proposed as theoretically feasible by microbiologists such as Van Niel (1946), but which had remained so elusive practically, was acknowledged to offer significant possibilities for bacterial systematics.

While the DNA-rRNA hybridization and rRNA oligonucleotide cataloguing methods were able to provide overviews of the phylogenetic relationships of bacteria, the proponents of the methods acknowledged their respective limitations in being able to differentiate the closely related organisms (Lane et al., 1985; Woese, 1987). To this end, complete sequence determinations of the rRNAs were envisioned as the means for establishing a phylogeny-based bacterial systematics with the resolution to differentiate even the most closely related organisms. The polymerase chain reaction (PCR; Mullis and Faloona, 1987), combined with advances in DNA sequencing (Hunkapiller et al., 1991), has enabled the determination and comparison of rRNA gene sequences (i.e., rDNA) to become a practical methodology in most microbiology laboratories for rapidly analyzing large numbers of organisms (Edwards et al., 1989). Thus, the number of prokaryotic small subunit (i.e., 16S) rRNA/rDNA sequences compiled in databases has grown from less than 300 in 1990 (Neefs et al., 1991) to more than 35,000 (nearly full-length), as of June 2004 see the Ribosomal Database Project - II (<http://rdp.cme.msu.edu>) (Cole et al., 2003). Of these, only five pseudomonad 16S rRNA sequences were available in 1990. Currently, more than 1300 16S rRNA/rDNA sequences of strains of *Pseudomonas* species are available in the public databases.

The differentiation and inferred phylogenetic relationships of the various pseudomonad rRNA similarity groups, as well as of the species included in each one of the groups, by comparative analysis of 16S rRNA gene sequences has been described in detail in two comprehensive reviews (Kerstens et al., 1996; Anzai et al., 2000). Not surprisingly, the phylogenetic relationships inferred from 16S rDNA sequence analyses corresponded with the earlier results determined by rRNA-DNA hybridization and rRNA cataloguing data. Thus, species retained within the genus *Pseudomonas* (sensu stricto) are observed to be those related to *P. aeruginosa*, in the Gammaproteobacteria, while other species are seen to cluster within genera of the Alphaproteobacteria

and Betaproteobacteria. The bacteria most closely related to the genus *Pseudomonas* include the species of the aerobic, free-living, nitrogen-fixing *Azotobacter*-*Azomonas* complex, cellulolytic species of the genus *Cellvibrio* and, somewhat more distantly related, marine bacteria of the genera *Microbulbifer* and *Marinobacterium*, endosymbiotic bacteria of the genus *Teredinibacter*, halophilic bacteria of the genera *Halomonas*, *Oceanospirillum* and *Marinomonas*, *Marinobacter* species isolated from marine environments, the Moraxellaceae family, and methylophiles of the Methylococcaceae (Kerstens et al., 1996; Anzai et al., 2000). These organisms exhibit quite diverse phenotypes and, on the basis of traditional analyses of phenotypic characteristics, probably would not be suspected as being the evolutionary “cousins” of *Pseudomonas*.

Taxonomy

The genus *Pseudomonas* comprises Genus I of the bacterial family Pseudomonadaceae. Five genera (*Pseudomonas*, *Azotobacter*, *Azomonas*, *Azorhizophilus* and *Cellvibrio*) are assigned to the family. Common to all constituent genera are certain physiological properties, such as aerobic, chemoorganotrophic metabolism, absence of fermentation, absence of photosynthesis, and capacity for growth at the expense of a large variety of organic substrates. There are a few exceptions to these general properties, but these phenotypic criteria are generally common to all members of the family.

The original creation of the genus *Pseudomonas* established a taxon based solely upon characteristics of cell morphology. At this point, it is appropriate to point out a discrepancy with respect to the publication date for the presentation of the genus. While the date for the publication of the genus *Pseudomonas* has been recognized as being 1894, Gunsalus (1996) and Zumft (1997) have pointed out previously that the genus was, in fact, presented for the first time in 1895 by Walter Migula at the Bacteriologischen Institut der Technischen Hochschule zu Karlsruhe in his publication of a seven-year effort, “Ueber ein neues System der Bakterien” (Migula, 1895), to describe and compare all known bacteria. The initial description of *Pseudomonas* by Migula was based solely upon morphological characteristics, as follows (translation):

Genus *Pseudomonas* nov. gen.

Cells with polar flagella. Endospore formation occurs in some species, but infrequently (e.g., *Pseudomonas violacea*).

This “succinct” description established the new genus within the family Bacteriaceae, accommodating bacteria on the basis of characteristic flagella type and the greenish or blue-green fluorescent pigment of the pus collected in bandages of hospital patients and wounded soldiers. A more comprehensive description of the genus followed in 1900 (Migula, 1900), including 75 species and registering *Pseudomonas aeruginosa*, previously described as “*Bacterium aeruginosum*” (Schroeter, 1872), as the type species of the genus.

Winslow et al. (1917) established the family Pseudomonadaceae, encompassing the genus *Pseudomonas* and a number of other genera, many of which have been reclassified throughout the following years. Many of the species of genera that were categorized within the family Pseudomonadaceae have come to be regarded as “pseudomonads” and, by association, related to *Pseudomonas*. This has proven often to be a source of confusion. Two terms should be defined at this point to clarify an important nomenclatural distinction that is often confusing. “*Pseudomonas*” (capitalized and written in italics) is the validly published (i.e., with nomenclatural standing) name of a bacterial genus comprising species of defined collective phenotypic characteristics. On the other hand, “pseudomonad” (not capitalized and not italicized) is a descriptive term (i.e., *Pseudomonas*-like), with no formal nomenclatural status, accorded to a nonexclusive collection of bacteria exhibiting various levels of similarity to species of the genus *Pseudomonas*. Pseudomonad bacteria previously characterized according to a limited selection of traits may have been observed to be similar to bacteria previously identified (correctly or incorrectly) as *Pseudomonas* species. Unfortunately, taxonomic convention, combined with a degree of uncertainty associated with the identifications of some pseudomonad bacteria, has led to the point that the terms “*Pseudomonas*” and “pseudomonad” are sometimes used interchangeably and incorrectly.

In the eighth edition of *Bergey's Manual of Determinative Bacteriology*, 29 well-characterized species of *Pseudomonas* were listed, with another 206 less well-described species included as addenda (Doudoroff and Palleroni, 1974a). This was the first compilation of the Bergey's series that incorporated molecular data, i.e., the G+C content of genomic DNA (Marmur and Doty, 1962), in the descriptions of the bacterial species. However, the level of taxonomic resolution that genomic DNA mol% G+C could afford was limited and, at that time, the data were handled simply as an additional determinative characteristic without any systematic weight.

The Approved Lists of Bacterial Names published in the *International Journal of Systematic Bacteriology* in 1980 (Skerman et al., 1980), provided an inventory of bacterial species names described before 1980 that were recognized as having formal nomenclatural standing under the auspices of the International Code of Nomenclature of Bacteria (1976 Revision). The list included 87 *Pseudomonas* species, effectively reducing the number of *Pseudomonas* nomenspecies by not including names that were inconsistent with the rules of the Code.

In 1984, in the first edition of *Bergey's Manual of Systematic Bacteriology*, a listing of 94 *Pseudomonas* nomenspecies was presented (Palleroni, 1984b). Many of the species were included with the recognition that their taxonomic relationships were unclear but with the expectation that comprehensive analyses would conclusively define their taxonomic positions. Within the first edition of *Bergey's Manual of Systematic Bacteriology*, perhaps the most significant contribution to the taxonomy of *Pseudomonas* was the presentation of the subdivision of the genus on the basis of rRNA similarities and estimations of phylogenetic relatedness (Palleroni et al., 1973; Palleroni, 1984). The five distinct "rRNA homology" groups were: 1) rRNA group I—*P. aeruginosa*, *P. fluorescens*, *P. putida* and related species, also termed the "true" *Pseudomonas* (i.e., *Pseudomonas sensu stricto*); this group included species observed to cluster within Woese's γ -subdivision of the Proteobacteria (Woese et al., 1985; Stackebrandt et al., 1988); 2) rRNA group II—*P. cepacia*, *P. mallei* and related species (to be reclassified as *Burkholderia*) and *P. solanacearum*, *P. picketti* and related species (to be reclassified as *Burkholderia* and, subsequently, as *Ralstonia*); this group included species observed to cluster within Woese's β -subdivision of the Proteobacteria (Woese et al., 1984); 3) rRNA group III—*P. testosteroni* and related species (to be reclassified as *Comamonas*), *P. acidovorans* and related species (to be reclassified as *Comamonas* and, subsequently, as *Delftia*), *P. facilis* and related species (to be reclassified as *Acidovorax*), *P. palleronii* and related species (to be reclassified as *Hydrogenophaga*), and *P. saccharophila* (not reclassified, to date); this group included species also observed to cluster within Woese's β -subdivision of the Proteobacteria; 4) rRNA group IV—*P. diminuta* and *P. vesicularis* (to be reclassified as *Brevundimonas*); this group included species observed to cluster within Woese's α -subdivision of the Proteobacteria (Woese et al., 1984); and 5) rRNA group V—*P. maltophilia* (reclassified as *Xanthomonas* and, subsequently, as *Stenotrophomonas*); this group included species observed to cluster also within Woese's γ -subdivision of

the Proteobacteria but clearly distinct from *Pseudomonas*.

These data effectively established the framework for the modern taxonomy of *Pseudomonas*, as well as other pseudomonads. Since then, many of the organisms described initially as species of *Pseudomonas* have been reclassified and new species have been added to the genus, largely because of the ability to recognize the phylogenetic relationships that have been determined through genotypic characterization. *Pseudomonas*, described in the second edition of *Bergey's Manual of Systematic Bacteriology* (Palleroni, 2004), comprises 61 species, representing the number of species of the genus that were available in the literature until the end of year 2000. Since the beginning of year 2001 until the time of this writing (June 2004), 30 new species of *Pseudomonas* have been described and the names validly published.

The taxonomic status of *Pseudomonas*, including the reclassifications of species formerly included within the genus, and the addition of new species, can be observed on-line through the internet at two principal sites: 1) the Deutsche Sammlung von Mikroorganismen und Zellkulturen (DSMZ) site for "Bacterial Nomenclature Up-to-Date" (<http://www.dsmz.de/bactnom/bactname.htm>); and 2) the (<http://www.bacterio.cict.fr/site/>) of the École Nationale Vétérinaire, "J.P. Euzéby "List of Bacterial Names with Standing in Nomenclature." These sites have compiled all the bacterial names of the "Approved Lists of Bacterial Names" (Skerman et al., 1980), as well as those that have been validly published since January 1, 1980.

Currently, *Pseudomonas* includes 156 species names that are recognized with nomenclatural standing, although 48 of these species have been reclassified and are now considered to be basonyms or synonyms of species placed in other genera (Table 1). Two species, *P. aureofaciens* and *P. perfectamarina*, are recognized as later heterotrophic synonyms of *P. chlororaphis* and *P. stutzeri* (genomovar 2), respectively. Another 10 species are recognized as not belonging to *Pseudomonas* (*sensu stricto*) but have not been reclassified as yet. At the time of this writing, 96 species have been described and recognized as belonging to the genus *Pseudomonas* (*sensu stricto*) and are listed with names of nomenclatural standing.

Habitat

Pseudomonas is a genus of truly ubiquitous organisms, which seems to be a consequence of their simple nutritional requirements, the range

^aValidly published names of species of the genus *Pseudomonas*, species names that have not been validly published are not included.

^bReclassification names in parentheses indicate that a reclassification has not been formally proposed.

^cAccession numbers are given only for species of *Pseudomonas* (sensu stricto).

^dSpecies that should not be included within the genus *Pseudomonas*.

^e*P. aeruginosa* is the type species of the genus.

^f*Pseudomonas* species that should be reclassified with a new species name.

of carbon compounds they utilize, and their genetic and metabolic adaptability. *Pseudomonas* species have a wealth of habitats available to it, ranging from various soil and water environments to plant and animal tissue. Essentially, any habitat with a temperature range of 4–42°C, a pH between 4 and 8 and containing simple or complex organic compounds is a potential habitat for *Pseudomonas*. *Pseudomonas* species are aerobes and the requirement for oxygen is

apparently the major constraining factor for habitation by *Pseudomonas*.

In fact, *Pseudomonas* species are generally found in soils and water environments that have aerobic, mesophilic and neutral pH conditions. In nature, *Pseudomonas* species exist as saprophytes and parasites. In general, they are not prominent in anaerobic environments, and they do not occur in extreme thermophilic or acidophilic habitats. On the basis of the data

derived from cultivation-dependent analyses such as selective enrichments and isolations, *Pseudomonas* would appear to occupy a prominent position in nature.

The conditions under which *Pseudomonas* species survive in soil are also favorable for growth of aerobic actinomycetes of the genus *Streptomyces* (prominent in the degradation of complex organic compounds) as well as many other types of bacteria. Soil-dwelling *Pseudomonas* grow in association with the streptomycetes and other bacteria, which may be providing them with monomeric carbon sources for growth.

The phytopathogenic *Pseudomonas* generally can be found only on diseased plants, in which they appear as relatively homogeneous populations when the pathological lesions are young. The distribution of many of these pathogens outside their host plants is poorly known, although many seem to be able to exist as saprophytes, as well.

Pseudomonas species play important roles in the food industry, where spoilage of meats, poultry and fish occurs, even under refrigerated conditions (Barrett et al., 1986). Some species of *Pseudomonas* are found in tap water and in hospital saline solutions, which are presumably devoid of nutrients (Van der Krooij, 1977). *Pseudomonas* can be particularly problematic in the development of biofilms within pipelines. New species of *Pseudomonas* have recently been isolated from relatively oligotrophic mineral water sources (Elomari et al., 1996; Dabboussi et al., 1999; Verhille et al., 1999; Ivanova et al., 2002).

Bacteria, including *Pseudomonas* species, traditionally have been studied as “planktonic forms” in cultures of broth media. However, bacteria surviving in various natural ecosystems are observed to live in small or extensive biofilm environments (Tolker-Nielsen and Molin, 2004). Quorum-sensing appears to play important roles in the development of biofilms, through the sensing of population densities and the exertion of some control in the expression of genes involved in the various stages of biofilm development (Whiteley et al., 2001).

This section describes some of the various habitats and niches of *Pseudomonas* species. While this treatment is relatively general, recent reviews have presented much more detailed overviews of the soil, rhizosphere and phyllosphere habitats of *Pseudomonas* (Bailey, 2004; Lugtenberg and Bloemberg, 2004; Sørensen and Nybroe, 2004).

Pseudomonas in Soil Environments

The soil environment may comprise the most complex of environmental niches that are

encountered by microorganisms. The heterogeneity of factors for growth in a soil presents the bacteria a challenging matrix of aggregate surfaces and pore structures. As the relationships between soil, plants and microbes are so intricately interwoven, it is difficult to obtain consistent overviews of the relevant microorganisms that are clearly demarcated between bulk soil and rhizosphere soil. *Pseudomonas* species, as well as species of many other pseudomonad genera, are clearly impacted by the rhizosphere influence.

Soil-dwelling *Pseudomonas* species are distributed throughout the world and, in general, may be observed to comprise similar rRNA sequence types and similar rRNA gene intergenic spacer (IS) types, as determined from a worldwide sampling of fluorescent species of *Pseudomonas* for assessing the inherent endemicity of microbial populations (Cho and Tiedje, 2000). However, at the level determined by genome fingerprinting (BOX-PCR) analyses, i.e., the strain level, *Pseudomonas* may be seen to comprise endemic populations that are determined by the specific transects of sampling sites.

A predominant question in microbial ecology is related to the actual presence and abundance of bacterial taxa within the respective ecosystems. Estimates suggest that cultivations are able to detect less than 1% of the total microbial populations in soil samples. Thus, while *Pseudomonas* species are able to be isolated from most soil samples, still unclear is whether the results obtained from enrichments and isolations reflect the situations in situ. In general, studies of various bulk soil ecosystems, employing cultivation-independent analyses of bacterial diversity, do not reflect the diversity or proportion of *Pseudomonas* species that are normally obtained by cultivation-dependent approaches. Even in xenobiotic-contaminated soils, which readily yield a diversity of isolates of *Pseudomonas* species, cultivation-independent approaches suggest that other bacterial taxa are numerically more predominant and that *Pseudomonas* may play only a minor role (Nogales et al., 1999; Nogales et al., 2001). However, such observations may not be contradicting the true nature of *Pseudomonas* species, as saprophytes and parasites. Even though *Pseudomonas*, as a group, may be observed to take advantage of its diverse metabolic potential and simple nutrient requirements, various *Pseudomonas* species, with their relatively rapid growth, may discover that they are less able to compete in bulk soil environments with other bacterial taxa that may be better adapted to dispersed levels of nutrients and that may possess various strategies for withstanding periods of “starvation”. While the soil ecosystem may appear to offer a diversity of

nutrient resources for microorganisms to use, the bioavailability of those resources, which may be complexed with inorganic matrices, also play an important role in selecting for which bacterial taxa are able to thrive in any given soil ecosystem. A comparative study of the bacterial taxa within bulk soil samples and in earthworm (*Lumbricus rubellus*) casts demonstrated significant differences in the numbers of *Pseudomonas* species detected, which was believed to be related to the nutrients available to the microorganisms during passage through the gut (Furlong et al., 2002). Limited available resources that may be obtained within bulk soil environments may not actually afford *Pseudomonas* species their best options and they may be more adapted to occupy an ecological niche as opportunistic scavengers in more nutrient-rich environments.

Pseudomonas in Association with Plants

The rhizosphere is referred to as a “zone” influenced by plants (Hiltner, 1904). This zone around the roots of plants is one of intense microbial activity, due to the secretion of organic and amino acids by the plants. *Pseudomonas* species are among the most competent rhizosphere colonizers of soil (Lugtenberg et al., 2001). Lugtenberg and Bloembergen (2004) have described the traits necessary for successful rhizosphere colonization, i.e., motility and chemotaxis, specialized pili for attachment to surfaces, lipopolysaccharide (LPS) and outer membrane integrity for efficient uptake of nutrients, ability to synthesize vitamins and macromolecule building blocks, ability to utilize specific exudate components, resistance to toxins, and other plant defenses. *Pseudomonas* species, in general, possess all of these traits, which provide them with a selective advantage for exploiting the resources in the rhizosphere. *Pseudomonas* species also effectively inhibit the colonization of plants by other microorganisms (Bianciotto et al., 1996). Thus, *Pseudomonas* is seen as an important agent for biocontrol of plant diseases.

In addition to the microbial communities below ground, an extensive diversity of microorganisms (epiphytes) populate and interact with the surfaces of plants (phyllosphere), primarily the leaves. Bacteria that have adapted to life in the phyllosphere must possess characteristics that protect them from exposure, as well as nutrient and water limitations (Bailey, 2004). Mercier and Lindow (2000) have demonstrated the availability of amino acids, carbohydrates and organic acids that leach from the interior of the leaf to the exterior, providing significant levels of nutrients to plant surface colonizing

bacteria. Bacteria appear to exist on plant surfaces, predominantly, as biofilms (Morris et al., 1998).

Epiphytes, including *Pseudomonas* species, may affect plant productivity negatively, e.g., through induction of frost injury (Lindow, 1995), or positively, e.g., by production of phytohormones that enhance development (Brandi et al., 2001). Just as specific traits enable certain bacteria to colonize successfully the rhizosphere environment, traits have also been identified that are associated with epiphytic fitness. Some of these traits are correlated with locations on leaf surfaces of pathogenic (i.e., *P. syringae*) and non-pathogenic species, and with the ability of the pathogens to access and multiply in protected sites of the phyllosphere (Wilson et al., 1999).

The phytopathogenic species of *Pseudomonas* are diverse with respect to their genetics, ecology, and the diseases they cause. One species, *P. syringae*, includes more than 50 pathovars, most of which specifically colonize different plant hosts. Phytopathogenic *Pseudomonas* species are distributed worldwide, causing diseases of most major groups of higher plants. Besides the pathogenic associations, *Pseudomonas* species also exist in other types of associations with plants. Some species affect plant growth through their inhibition of fungal plant pathogens or by their effects on the roots of plants. *Pseudomonas* species may further colonize other plant parts, with no apparent damage or benefit to the plant (Lodewyckx et al., 2002).

Isolation

Pseudomonas species, in general, have simple nutritional requirements and are readily isolated from a variety of environments. In the laboratory they grow well in media containing some organic matter in solution, at neutral pH, and at temperatures in the mesophilic range. The optimal growth temperature for *P. aeruginosa*, the most likely species to be encountered in medical specimens, is 37°C. However, species of *Pseudomonas* grow well at 28–30°C, which is more appropriate for most of the species.

The range of nutrient sources that are used by *Pseudomonas* is extensive and species of *Pseudomonas* tend to grow relatively rapidly, often outgrowing the species of other genera. Most species of *Pseudomonas* favor a rich medium, such as nutrient broth and agar or tryptic soy broth and agar and other media rich in peptides, although different numbers and diversity of *Pseudomonas* species may be obtained with different peptide concentrations in the media (Aagot et al., 2001). Saprophytic species of *Pseudomonas* can be isolated by streaking

samples on nutrient agar or tryptic soy agar plates. Denitrifying *Pseudomonas* species are be isolated by specific enrichment procedures in a medium containing nitrate (NO₃), under anaerobic conditions, at 30–40°C.

Most *Pseudomonas* species grow in chemically defined media without added growth factors. With the reorganizations of the taxonomy of *Pseudomonas*, species known to require special growth supplements are now recognized as belonging to separate and distinct evolutionary lineages. No particular minerals or vitamins are necessary for supporting growth of species of *Pseudomonas* (sensu stricto).

A medium described by Palleroni and Douderoff (1972), developed for autotrophic and heterotrophic enrichments, functions well for the cultivation of *Pseudomonas*. *Pseudomonas* species grow well also on mineral medium used for isolating *Arthrobacter* (Owens and Keddie, 1969) and on R2A mineral medium for oligotrophic growth (BBL Microbiology Systems, Cockeysville, MD). In general, good growth of *Pseudomonas* species is observed in media including organic compounds from 0.1–1.0% (w/v) as carbon and energy sources.

Cultivation media that have been used for selective enrichments of *Pseudomonas* species may be deficient in iron, enabling the detection of fluorescent *Pseudomonas* species. The fluorescence is due to increased production of siderophore pigments extruded into the media. Other media have employed antibiotics, such as penicillin G, novobiocin and cycloheximide, which do not inhibit fluorescent *Pseudomonas* species (Sands and Rovira, 1970).

Selective media used extensively for the detection and isolation of fluorescent *Pseudomonas* species are King's media A and B (King et al., 1954), which employ potassium and magnesium salts to enhance pyocyanin and pyoverdine pigment production. Gould's S1 medium contains sodium lauroyl sarcosine, which effectively inhibits the growth of Gram-positive bacteria. The antibiotic trimethoprim may be included in the medium to inhibit nonfluorescent pseudomonads (Fromin et al., 2001). Other selective-differential media that support *Pseudomonas* growth include Pseudoselect agar medium (BBL Microbiology Systems), Cetrimide agar medium, *Pseudomonas* isolation agar medium and *Pseudomonas* agar F medium (Difco Laboratories, Detroit, MI) containing cetyltrimethylammonium bromide (Cetrimide or CTAB), 2,4,4-trichloro-2-hydroxydiphenyl ether (Irgasan), or similar compounds, although *Pseudomonas* species are isolated in lower numbers and diversity on the strongly selective media (Gilardi, 1985). The use of Cetrimide was recommended (Lowbury, 1951) for inhibiting the

growth of accompanying microbial flora and minimizing interference with the growth of *P. aeruginosa*. The pigment production of *P. aeruginosa* is not inhibited when grown on this medium. Addition of nalidixic acid (Goto and Enomoto, 1970) improves further the inhibition of accompanying microbial flora.

As Schroth et al. (1992) have pointed out, the choice between a general or selective medium for isolation of *Pseudomonas* depends upon the samples to be analyzed. Selective media are recommended for samples from soil, water and organic materials that contain many other microorganisms, whereas general growth media will be more useful for obtaining larger numbers and diversity of isolates from sources exhibiting strong selective pressures already.

Recently, new species of *Pseudomonas* have been isolated from various soil types (Delorme et al., 2002; Kwon et al., 2003), rhizosphere (Achouak et al., 2000), phyllosphere (Behrendt et al., 1999), water (Elomari et al., 1996; Dabboussi et al., 1999; Verhille et al., 1999; Ivanova et al., 2002), and Antarctic cyanobacterial mats (Gundlapalli et al., 2004), as well as by the application of some uncommon selection protocols, including, the use of resin acids, which may be biologically toxic (Mohn et al., 1999), chlorate as a terminal electron acceptor and acetate as an electron donor (Wolterink et al., 2002), and cooking water from a cork-processing factory at 50°C (Manaia and Moore, 2002).

Identification

Straight or slightly curved rods but not helical, 0.5–1.0 µm in diameter by 1.5–5.0 µm in length. Most of the species do not accumulate granules of poly-β-hydroxybutyrate, but accumulation of poly-hydroxyalkanoates of monomer lengths higher than C₄ may occur when growing on alkanes or gluconate. Do not produce prosthecae and are not surrounded by sheaths. No resting stages are known. Gram-negative. Motile by one or several polar flagella; rarely nonmotile. In some species, lateral flagella of short wavelength may also be formed. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor; in some cases nitrate can be used as an alternate electron acceptor, allowing growth to occur anaerobically. Xanthomonadins are not produced. Most, if not all, species fail to grow under acid conditions (pH 4.5 or lower). Most species do not require organic growth factors. Oxidase-positive or negative. Catalase-positive. Chemoorganotrophic. Strains of the species include in their composition the hydroxylated fatty acids 3-OH 10:0 and 12:0, and 2-OH 12:0, and ubiquinone Q-9.

Widely distributed in nature. Some species are pathogenic for humans, animals or plants. The mol% G+C content of the DNA is 58–69. Type species: *Pseudomonas aeruginosa* (Schroeter 1872) Migula 1900, 884.

The above is the definition of *Pseudomonas*, as it appears in the second edition of *Bergey's Manual of Systematic Bacteriology* (Palleroni, 2005). Characterizations of bacteria, including *Pseudomonas*, must address at least two aspects for purposes of identification. The first has to do with the characterization of *Pseudomonas* (sensu stricto) and differentiation from other genera, including those species that were classified as *Pseudomonas* in the past. The second has to do with resolving the intrageneric subdivisions of *Pseudomonas* (sensu stricto) into species. A complicating factor for such analyses is that species of the genus *Pseudomonas* and other pseudomonads are well known for their “promiscuity” in exchanging to exchanging genetic material. Questions of whether observed traits are stable, reliable and truly characteristic of a given organism become relevant for taxonomic and identification purposes.

The “species” is the basic unit of classification in biology and, as well, has been applied in microbiology, albeit relatively inconsistently. The intrageneric units in microbiology have been accepted somewhat empirically and guidelines for determining what is necessary for describing a bacterial species in any systematic manner have only recently evolved. Rosselló-Mora and Amann (2001) have discussed the complexities of conceptualizing the prokaryotic species, and have proposed guidelines for categorizing what they have termed the “phylo-phenetic species,” i.e., “a monophyletic and genomically coherent cluster of individual organisms that show a high degree of overall similarity with respect to many independent characteristics, and is diagnosable by a discriminative phenotypic property.”

The genus *Pseudomonas* comprises a group of species for which the amount of information available is quite uneven. It is relatively vast in the case of the type species of the genus, *P. aeruginosa*, primarily because of its medical importance as an opportunistic pathogen. However, markedly less is known about other species of the genus, particularly those isolated recently from some relatively uncommon sources. Perhaps, owing to better recognition of the properties useful in determinative schemes, the isolation of bacteria, such as *P. mendocina*, *P. stutzeri* and other *Pseudomonas* species, are being reported with increasing frequency from clinical samples. Generally speaking, *Pseudomonas* has a well-deserved reputation for a variety of beneficial biotechnological properties. In the case of *P. fluorescens* and *P. putida*, catabolic

properties have dominated other details of *Pseudomonas* biology, including the recently growing amount of information on the effect of these species on stimulating plant growth. *P. fluorescens* and *P. putida* are represented in nature by several biovars, and the species names lack precise systematic definition. However, the genus also is notorious because of species that are opportunistic pathogens of humans as well as phytopathogens that significantly impact the agricultural and economic well-being worldwide.

While some species of the genus *Pseudomonas* (e.g., *P. aeruginosa*) are homogeneous taxonomic units that are relatively easily differentiated and identified, other species include complex subdivisions, such as the *P. fluorescens* and *P. putida* biovars, the *P. syringae* and *P. marginalis* pathovars, or the *P. stutzeri* genomovars. Such internal organization of the genus is a reflection of the heterogeneity of bacteria that have been studied extensively and whose characteristics have not conformed completely to recognized taxonomy. Discrepancies between phenotypic and genotypic properties have further hindered attempts to resolve the systematics. However, given these complications in bacterial taxonomy, the “species” remains the biological unit that purports to represent a systematic description of an organism's basic properties.

Traditional and more recent characteristics applicable to *Pseudomonas* identification at the genus and subgenus levels are described below.

Cell Morphology

Pseudomonas species are straight or slightly curved rod-shaped cells (maximum length ca. 4.0 μm) that occur singly or in pairs or short chains. Their morphology may occasionally deviate from that in standard descriptions. The cells typically stain Gram-negative. Electron microscopy reveals cell walls and membranes typical of Gram-negative bacteria, although different species may exhibit different chemical compositions. The cells of many of the species lyse readily in EDTA solution, which correlates generally with the high phosphorous content of the outer membranes (Wilkenson, 1970). Many species of *Pseudomonas* have been observed to produce poly- β -hydroxybutyrate (PHB) granules, particularly when grown under nitrogen-limiting conditions. The traditional description of a short rod-shaped cell does not always fit the morphology of all strains of *Pseudomonas* species. The cells of some strains can be extremely short, while in others (*P. putida* and *P. syringae*) they may be unusually long. Particularly in the cases of older cultures, the cells may be of unusual shapes and sizes.

With few exceptions, flagellar motility is a common characteristic of *Pseudomonas* species. Motility allows the cells to respond to chemical stimuli (chemotaxis) and enhances the ability of the bacterium to locate organic substrates at low concentrations. The majority of *P. aeruginosa* cells have only one flagellum, although exceptional *P. aeruginosa* cells with two or three flagella have been observed. *P. alcaligenes*, *P. mendocina*, *P. pseudoalcaligenes* and *P. stutzeri* are also characterized by having a single flagellum per cell. Most other species possess more than one. However, variations are observed in the flagellation of strains of *Pseudomonas* species and nonmotile strains may be isolated occasionally. The flagellar number of *P. aeruginosa* is reported to be controlled by FleN, a putative ATP-GTP binding protein, and the disruption of the *fleN* gene results in multiflagellation of otherwise monoflagellated strains, as well as in chemotactic defects (Dasgupta et al., 2000). The flagella are inserted at the poles of cells, although some exceptions have been observed, e.g., in *P. stutzeri* (Palleroni et al., 1970). Lateral flagella are thought to participate in swarming activity of cells (Shinoda and Okamoto, 1977).

Pili are observed in many Gram-negative bacteria, functioning as appendages for attaching to cell surfaces (Buchanan and Pearce, 1979). Pili have been studied extensively in *P. aeruginosa*, primarily because of their involvement in pathogenesis (i.e., as components of virulence factors), although the structures of these cell appendages are not known for most other species. Pili have been observed also in strains of *P. alcaligenes*. On the other hand, no pili have been observed in cells of *P. chlororaphis*, *P. fluorescens*, *P. oleovorans* or *P. putida*.

The low G+C content of the pilin genes in *P. aeruginosa* suggests that they may have been transmitted by horizontal transfer and, as a consequence, have a different pattern of codon usage (West and Iglewski, 1988).

A common characteristic of the fluorescent pseudomonads is the production of pigments that fluoresce in short wavelength (254 nm) ultraviolet light, particularly after growth under iron limitation. Some of these pigments and their derivatives are known to act as siderophores in these bacterial iron uptake systems (Meyer et al., 2002). The production of pigments by *Pseudomonas* species is demonstrated by cultivating the bacteria in media such as King's medium B, which contains no added iron. The medium is also recommended for demonstrating the production of the nonfluorescent blue pigment, pyocyanin, characteristically produced by most strains of *P. aeruginosa*. While *P. aeruginosa* is the most notable species of *Pseudomonas* for the production of distinctive pigments, other spe-

cies are known to produce soluble and insoluble pigments that may be diagnostic. Pyoverdine (yellow-green fluorescence) represents the main siderophore type of *Pseudomonas* species. (Meyer and Hornsperger, 1998). The taxonomic value of siderophore-typing appears to lie in the species- and strain-specificities. The results of siderophore-typing of a large number of fluorescent and nonfluorescent strains correlated with the results of genotypic analyses, indicating that this approach is promising for differentiation at the species level (Fuchs, 2001; Meyer et al., 2002). Other pigments produced by species of *Pseudomonas* include pyocyanin (*P. aeruginosa*, blue color), pyorubin (*P. aeruginosa*, red color), oxochlororaphin (*P. aureofaciens*, orange color), chlororaphin (*P. chlororaphis*, green color), oxychlororaphin (*P. chlororaphis*, orange color), etc. (Hugh and Gilardi, 1980).

The basic morphological characteristics of *Pseudomonas* are common to many families of bacteria and so are of little value in the positive identification or diagnosis of members of the genus.

Nucleotide Base Composition of Genomic DNA

The first genotypic analysis applied in bacterial characterization (Lee et al., 1956), the nucleotide base ratio of genomic DNA is measured as the ratio of the amount of guanine and cytosine nucleotides to the total amount of nucleotide bases (i.e., % G+C). Among prokaryotes, the G+C content ranges between 22–74 mol% (Marmur et al., 1963) and has proven to be useful for differentiating some taxa that are phenotypically similar. Although no exact guidelines have been established, generally, the G+C content has been reported to vary no more than 10 mol% within a bacterial genus (Stackebrandt and Liesack, 1993). Among the *Pseudomonas* species (*sensu stricto*), the range of G+C content is ca. 59–68 mol%, while among species reclassified within new genera, the range of G+C is 65–69 mol% for *Burkholderia* species, 64–68 mol% for *Ralstonia* species, 62–70 mol% for *Acidovorax* species, 62–67 mol% for *Comamonas* species, 65–67 mol% for *Brevundimonas* species, etc. (Palleroni, 1984). Though markedly different genomic DNA G+C contents certainly reveal different bacterial taxa, similar G+C contents do not necessarily indicate genomic relatedness.

Ribosomal RNA Gene Sequences

During the last decade, a concerted movement in microbial taxonomy has adopted phylogenetic relationships inferred from genotypic analyses, particularly those derived from rRNA and

rRNA gene (rDNA) sequence analyses, as an important component of a taxonomic “framework”. Analyses of rRNA-rDNA sequence similarities of bacteria have been essential for elucidating their intergeneric relationships, and sequence determinations and analyses of 16S rRNA genes are among the recommended minimal standards for descriptions of new species. However, the application of rRNA-rDNA sequence analysis for determining intrageneric relationships of bacteria has not proven to be as successful. Given the early optimism for applying a principle of “one rRNA sequence type = one bacterial species,” the reality observed in the last decade has proven to be sobering in light of the conservative nature of the rRNAs, which have proven to be limited in resolving the fine bacterial phylogenetic structure below the genus level. Stackebrandt and Goebel (1994) assessed the relationships between genomic DNA-DNA similarity (determined by hybridization) and 16S rRNA gene sequence similarities, and they have described the levels of 16S rRNA gene sequence similarity (or dissimilarity) that indicates when a bacterium does not belong to a given species. However, a definition of bacterial species based upon 16S rRNA-rDNA sequence similarities still is not established.

The limitation in achieving definitive resolution of bacterial species does not suggest that 16S rRNA-rDNA cannot be useful for estimating intrageneric relationships. Suffice it to say that 16S rRNA gene sequences have been used to demonstrate considerable internal evolutionary structure within the spectrum of *Pseudomonas* species (*sensu stricto*; Moore et al., 1996; Anzai et al., 1997; Anzai et al., 2000). Moore et al. (1996) detected at least two distinct intrageneric divisions designated, for want of better labels, 1) the “*P. aeruginosa* intrageneric cluster” and 2) the “*P. fluorescens* intrageneric cluster.” Most species of *Pseudomonas* (isolated and characterized to date) group within one of these two clusters. Furthermore, *Pseudomonas* species were observed to be linked through distinct “evolutionary lineages” within the primary dichotomy of the genus. The same overall topography of the two major clusters, as well as the relationships of species comprising the evolutionary lineages, with some exceptions, has been observed in subsequent phylogenetic reconstructions (Anzai et al., 2000). Admittedly, the *Pseudomonas* intrageneric clusters and evolutionary lineages mentioned here comprise inferred natural branching orders. However, the organization of the two major intrageneric clusters, as well as the species comprising the evolutionary lineages, have been observed also in nonribosomal RNA-based analyses, using fatty acid methyl ester (FAME) and phospholipid fatty acid profiling

(Vancanneyt et al., 1996b), or sodium dodecylsulfate-polyacrylamide gel electrophoresis SDS-PAGE analysis of whole cell proteins (Vancanneyt et al., 1996a). Questions exist as to whether *P. putida* and closely related species, as well as some newly isolated species, are included as evolutionary lineages within one of the two primary intrageneric clusters or comprise separate, distinct intrageneric clusters.

Pseudomonas pertucinogena and “*P. denitrificans*” are seen to branch clearly outside the phylogenetic spectrum of all other species of the genus (Anzai et al., 2000), raising the question as to their taxonomic placement. “*P. denitrificans*” was placed on the list of nomina rejicienda (rejected synonyms) as a nomen ambiguum, because of previous confusion regarding its taxonomic position (Doudoroff et al., 1974b). Until comprehensive, polyphasic analyses of these two organisms has been carried out and their proper taxonomic positions confirmed, it is premature to include either species within the genus *Pseudomonas* (*sensu stricto*).

With the increase in *Pseudomonas* species isolated and characterized by 16S rRNA gene sequence comparisons, the resolution between the individual sequences of the species has decreased and the branching orders have become less discernible. Such observations led to a significant problem in using rRNA-rDNA sequences for species identifications. Overall, 16S rRNA gene sequence similarities between species of *Pseudomonas* range from approximately 93% to 99.9% (given some unknown degree of error in sequencing results, 16S rRNA gene sequences of different species that may be identical cannot be ruled out). The complete 16S rRNA gene sequences are approximately 1540 nucleotides long. However, less than 10% (148 nucleotide positions) of the gene of *Pseudomonas* species appear to be susceptible to nucleotide base change and most of the positions that vary between species are located within hypervariable regions. Given these observations, if it were conceivable to apply the “one rRNA sequence type = one species” principle, the number of possible *Pseudomonas* species would be $(4)^{148}$ (where 4 = the number of nucleotides that can exist at any given variable position, and 148 = the number of variable nucleotide positions). However, bacteria of different species have been observed to possess identical 16S rRNA gene sequences (Fox et al., 1992). With such an observation on record, one cannot assume that a unique 16S rRNA gene sequence will characterize a single bacterial species. This premise, of course, has important consequences for *Pseudomonas* taxonomy and the analyses of *Pseudomonas* in studies of microbial ecology and diversity.

Another potential genotypic target for resolving the species of the genus *Pseudomonas* are the 23S rRNA genes. In general, the limited number of sequences that have been determined have indicated that the larger (ca. 2500 nucleotides) bacterial 23S rRNA genes possess a higher degree of sequence variation than do the 16S rRNA genes (Olsen, 1988). Christensen et al. (1994) analyzed selected, variable target regions within the 23S rRNA genes of some *Pseudomonas* species, and the data failed to provide a reliable basis for identifying closely related species. However, the number of analyses on the 23S rRNA genes of bacteria, including species of the genus *Pseudomonas*, has remained limited, and, as a result, their value for resolving the fine intragenetic relationships is not yet established.

The similarities in rRNA gene sequences and the phylogenetic relationships may be used, in turn, for developing diagnostic tools for detecting and identifying bacteria at the genus and species levels in environmental or clinical samples. The high specificity of nucleic acid probes and the different regions of the rRNA molecule, containing variable numbers of conserved sites, provide ready targets for oligonucleotides labeled with an appropriate molecule for in vitro or in situ detection of bacteria at different taxonomic levels (Amann et al., 1995). Genus- and species-specific oligonucleotide probes have been designed (Schleifer et al., 1992; Amann et al., 1996) that enable the detection of combinations of pseudomonad species from the different proteobacterial classes. However, a single set of hybridization probes for differentiating all species of the various pseudomonad genera or all species of the genus *Pseudomonas* has yet to be successfully developed. While it may be theoretically possible to differentiate bacteria on the basis of a single base change in a probe target region, the sequence regions exhibiting the nucleotide differences (i.e., "signatures") between species of a genus are limited in number, as well as in their structural availability to probing. Thus, Amann et al. (1995) have applied the practice of using nested probes in a "top-to-bottom" approach, whereby combinations of oligonucleotides used to differentiate organisms at different taxonomic levels systematically refine the levels of identification that may be determined. Such a strategy, which requires a large number of probes for identifying an organism of a specific sequence type, becomes realistic when used with micro-array hybridization systems.

In the same way that rRNA-rDNA sequence data have provided the means for developing hybridization probes as tools for differentiating bacterial species, the sequence data has also been used for devising PCR-diagnostic assays of high

specificity. Widmer et al. (1998) combined specifically targeted PCR-amplification assays with restriction fragment length polymorphism (RFLP) analyses to develop a rapid assay for detecting 16S rDNA sequence types that cluster within the phylogenetic spectrum of *Pseudomonas* species.

Genomic DNA Similarities

Genomic DNA-DNA reassociation similarities have been accepted for many years as the molecular standard by which bacteria are classified at the species level (Johnson, 1984). The "cut-off" levels of DNA-DNA similarity that are used to "define" strains of a species range from above approximately 60% similarity ($\delta T_{m(e)}$, 6–9°C to approximately 70% similarity ($\delta T_{m(e)}$, 5°C; Brenner et al., 2001).

The original DNA-DNA hybridization experiments were performed by McCarthy and Bolton (1963) and were applied at Berkeley to the analysis of the pseudomonads to complement the existing phenotypic data. The results further supported previous conclusions based upon phenotypic analyses pointing to a significant degree of heterogeneity and fundamental differences among the species assigned to *Pseudomonas*, as the genus was known at that time. Subsequent analyses supported the subdivision of the genus (Johnson and Palleroni, 1989).

rRNA Gene Intergenic Spacer (IS) Sequences

A potential target site for resolving intragenetic relationships of *Pseudomonas* may be found in the noncoding, intergenic spacer (IS) region between the 16S and 23S rRNA genes. This DNA is excised during the process of transcribing the ribosomal RNA during the synthesis of ribosomes and is, thus, exposed to less evolutionary conservation than the rRNA genes.

Tyler et al. (1995) were able to differentiate *P. aeruginosa* and *P. mendocina*, as well as different pseudomonad bacteria, to the species level by sequence comparisons of PCR-amplified 16S-23S rDNA IS regions. IS sequences from different strains of the same species did not exhibit sequence differences greater than 5% and, in most cases, were not more than 2% divergent. IS sequences of different species of the same genus exhibited significantly higher (25–20%) sequence dissimilarities.

Guasp et al. (2000) have used 16S-23S rDNA IS sequence characteristics to resolve the genovars of *P. stutzeri*, developing assays using restriction digestions of PCR-amplified IS regions, and correlating the results with differentiations determined by DNA-DNA hybridization

analyses. Although the IS sequence data for other species of *Pseudomonas* is sparse, these studies, and others analyzing various bacterial taxa, suggest that the results of sequence analyses of these DNA regions correlate well with results of DNA-DNA hybridization analyses and may offer an alternative to the DNA-DNA hybridization technique for identifying *Pseudomonas* and other bacterial species.

Housekeeping Gene Sequences

The use of conserved protein-coding gene sequences as molecular chronometers has met with varied success. In general, the rates of change are significantly greater than those observed for rRNA genes and the sequences have been proposed as alternatives for estimating close (i.e., intragenetic) phylogenetic relationships (Santos and Ochman, 2004). Probably the most comprehensive studies employing housekeeping gene sequence targets in *Pseudomonas* have come from analyses of the *gyrB* gene that encodes the β -subunit protein of DNA gyrase (topoisomerase type II; Yamamoto and Harayami, 1998; Yamamoto et al., 2000). The base substitution rates of *gyrB* within species of the genus *Pseudomonas* were observed to be greater than those of the 16S rRNA genes of the same organisms, presumably because of the number of sites available for neutral base substitutions. Interestingly, while the branching order of the most closely related bacteria, such as different strains of *P. putida*, was clearly much more defined by *gyrB* gene sequence comparisons than could be achieved with 16S rDNA sequences (Yamamoto et al., 2000), the overall branching order of the range of different species of *Pseudomonas* was observed to be essentially the same.

Studies targeting other genes with purported evolutionary chronometer characteristics and applied to *Pseudomonas* include the *rpoD* gene for the σ^{70} factor of the RNA polymerase (Yamamoto and Harayama, 1998) and the *narG* and *nosZ* genes for nitrate reductase and nitrous oxide reductase, respectively (Delorme et al., 2003). However, the number of species and strains analyzed in these studies has been too limited to be able to determine whether these genes provide reliable reconstructions of *Pseudomonas* phylogeny.

Santos and Ochman (2004) have argued that problems associated with relying upon a single gene, such as the 16S rRNA gene, with its inherent limitations, to estimate organismal phylogenies may be circumvented by typing multiple single-copy gene loci of selected "chronometer" proteins. While such multilocus sequence typing

(MLST) analyses have been carried out on some bacterial taxa, this approach has yet to be applied to the analysis of *Pseudomonas*.

Cell Lipid Compositions

The lipid composition of cell walls has been recognized to reflect the "natural relationships" between bacteria for nearly 40 years (Ikawa, 1967). Fatty acid, polar lipid, lipoquinone and polyamine profiles are regarded as valuable phenotypic markers of taxonomic value (Ratledge and Wilkinson, 1988; Tindall, 1994), although limited in their ability to resolve close relationships. Whole-cell fatty acid methyl ester (FAME) profile databases are now available as commercial products (e.g., the Microbial Identification System from Microbial ID, Inc. [Newark, DE]) and are used to identify bacteria at the genus level, in most cases, and subgenus levels in many cases.

In several laboratories, the compositions of cellular lipids of pseudomonads and other taxa have been described (Wilkinson et al., 1972; Moss and Dees, 1976; Ikemoto et al., 1978; Collins and Jones, 1981; Oyaizu and Komagata, 1983; Vancanneyt et al., 1996b). Whole-cell fatty acids of 16:0 and isomers of 16:1 and 18:1 appear to be typical of most Proteobacteria and are of limited diagnostic value in differentiating *Pseudomonas* (sensu stricto) from other genera (Vancanneyt et al., 1996b). *Pseudomonas* species have 3-OH 10:0, 3-OH 12:0 and 12:0, in addition to 16:1 ω 9c, 16:0 and 18:1 ω 7c, as their cellular fatty acids, as well as the Q-9 ubiquinone. Most species also have the saturated 12:0 2-OH component and no significant levels of 3-OH 14:0 (Vancanneyt et al., 1996b). A small number of species may also produce the 14:0 fatty acid. Although few analyses have been carried out on the polar lipid compositions of *Pseudomonas*, phosphatidyl glycerol, phosphatidyl ethanolamine, and diphosphatidyl glycerol (cardiolipin) have been observed as the major cell components, with a number of uncharacterized minor components also present. These comprise the typical cellular chemical compositions of *Pseudomonas* spp. (sensu stricto). The differential value of the lipid components of bacteria is found in the overall combinations of the lipid species, not necessarily in the presence of a single lipid biomarker. Furthermore, quantitative and qualitative differences in some lipid components (i.e., cellular fatty acids) also are valuable taxonomic markers for *Pseudomonas* species.

Alginate Production

Alginate is an exopolysaccharide (EPS) comprised of a linear β -1,4-linked polymer of D-

mannuronic acid and L-gluronic acid. Alginate is produced by some bacteria, most notably by *P. aeruginosa* infecting the lungs of cystic fibrosis patients and causing severe respiratory problems (Govan, 1988), as well as by phytopathogenic or plant-associated fluorescent *Pseudomonas* species (Fett et al., 1986).

The genes involved in alginate synthesis in *P. aeruginosa* have been cloned and analyzed. Screening of bacteria for alginate genes, using DNA probes that target four genes involved in alginate production, detected DNA sequences homologous to all *P. aeruginosa* alginate genes in the chromosomal DNA of many species of *Pseudomonas* (sensu stricto), with the exception of *P. stutzeri*, which reacted to three of the four probes (Fialho et al., 1990). All of the alginate genes analyzed were detected in *Pseudomonas* species and the *Azotobacter*-*Azomonas* lineage, but fewer numbers of the genes were found in the other pseudomonad species and enteric genera.

In a related study, the *trans*-activation of gene *algU*, which controls the conversion of *P. aeruginosa* to a mucoid phenotype, was observed to be caused by a mutation in gene *algN*, at an adjacent locus, the product of which, presumably, inhibits the regulation of alginate production (Goldberg et al., 1993). *Pseudomonas* species were screened by hybridizing homologous DNA fragments to a probe for *algU* from *P. aeruginosa* (Dubnau et al., 1965). Homologous sequences were detected in the DNA of rRNA homology group I *Pseudomonas* species (*P. fluorescens*, *P. putida*, *P. mendocina* and *P. stutzeri*) but not in *Comamonas acidovorans* (rRNA group III), *Brevundimonas diminuta* (rRNA group IV), or *Stenotrophomonas maltophilia* (rRNA group V).

These data suggest that alginate production may be a useful indicator for differentiating *Pseudomonas* (sensu stricto) from other bacteria, including other phenotypically similar pseudomonads.

Cellular Proteins

The comparison of amino acid sequences of selected homologous proteins offers the potential for assessing relationships among different bacterial genera (Schwartz and Dayhoff, 1978). However, protein sequence determinations are not a routine procedure. Thus, methods for determining the antigenic divergence of heterologous proteins, using antisera raised against reference proteins, can be used to identify amino acid sequence differences.

Glutamine synthetase, an important enzyme involved in nitrogen metabolism, has been the object of comparative immunological studies of

pseudomonads. The results of these studies were identical to those of the nucleic acid hybridization experiments (Baumann and Baumann, 1978). Other immunological studies of selected enzymes (such as muconolactone isomerase [Stanier et al., 1970], aliphatic amidases [Clarke, 1972], and histidine ammonia-lyases [Rokosu, 1983]) have determined the degrees of similarity among homologous proteins of pseudomonads. These studies have provided useful determinative applications and further confirmation of the internal subdivisions of *Pseudomonas* (Palleroni, 1975; Palleroni, 1993), although, in an immunological study of the relatedness of histidine ammonia-lyases (histidases) of *Pseudomonas* species, the anti-P antibody appeared to be diagnostic for fluorescent species of *Pseudomonas* but not for the nonfluorescent species (Robert-Gero et al., 1969).

Outer membrane proteins include three or four predominant proteins that can be discerned by electrophoresis and are conserved among species of rRNA homology group I *Pseudomonas* (Kragelund et al., 1996). An antibody raised against one of these proteins from a strain of *P. fluorescens* (OprF, 37 kDa) was used in Western blot screenings of isolates from rhizosphere samples, and specificity for rRNA homology group I *Pseudomonas* was confirmed.

Tesar et al. (1996) described another approach exploiting the immunological differentiation of characteristic cellular proteins in which whole cell protein electrophoresis patterns, reacted with antibodies of appropriate specificity in a Western blot, enable identifications over a wide phylogenetic range. Monoclonal antibodies generated against *Pseudomonas*-specific epitopes of outer membrane proteins were able to differentiate *Pseudomonas* species (sensu stricto) from species of closely related genera.

Such analyses appear to be applicable to different taxonomic levels, such as the differentiation of the genus *Pseudomonas* (sensu stricto), although the immunological approaches may be most useful for intrageneric identification, because of the potential for extremely high antibody specificity.

Substrate Utilization

Substrate utilization has been an essential criterion for fine-resolution differentiation of species (and strains) of *Pseudomonas*. The lists of substrates utilized by *Pseudomonas* species are extensive, and the pathways for metabolism have been reviewed comprehensively (Stanier et al., 1966; Palleroni and Douderoff, 1972; Palleroni, 1984a; Palleroni, 1984b; Palleroni, 1993). Nutritional screenings of *Pseudomonas* species have been used to assess the capacity for growth at the

expense of a variety of carbon compounds (Stanier et al., 1966) and the findings have demonstrated the metabolic versatility that has made the genus renowned since the beginning of the twentieth century (den Dooren de Jong, 1926). In one case, a single strain of *P. putida* was observed to utilize 77 of 200 compounds tested, including carbohydrates, alcohols, saturated and unsaturated fatty acids, amino acids, amides and amines (den Dooren de Jong, 1926). In a separate study (Palleroni et al., 1973), another strain of *P. putida* grew on 80 of 150 compounds tested.

Many aromatic compounds are used by *Pseudomonas* species as growth substrates. During the early analyses at Berkeley, these compounds were observed to be typically metabolized to a common intermediate, β -ketoadipate (3-oxoadipate), by the fluorescent species. Species associated with rRNA homology groups II-V used different pathways for the metabolism of various aromatic compounds, although the β -ketoadipate pathway is also followed by pseudomonads and other bacteria unrelated to *Pseudomonas* species. (*sensu stricto*; Stanier, 1968). The mechanisms of aromatic ring cleavage appear to be characteristic for the different pseudomonad rRNA homology groups. By using antibodies against crystalline preparations of two enzymes of the β -ketoadipate pathway, muconate lactonizing enzyme (muconate cycloisomerase) and muconolactone isomerase isolated from *P. putida*, heterologous reactions were observed in preparations from *P. putida* biovars, *P. aeruginosa*, all biovars of *P. fluorescens* and *P. stutzeri* but not in preparations from *B. cepacia* or species of the *Comamonas* group (Stanier et al., 1970).

Metabolism of Amino Acids

Different pathways leading to L-phenylalanine or L-tyrosine are conserved in bacterial taxa (Byng et al., 1982) and analysis of key enzymatic features in these pathways, such as 2,4-diamino-6-hydroxypyrimidine (DAHP) synthase, prephenate dehydrogenase, arogenate dehydrogenase, prephenate dehydratase and arogenate dehydratase, have been used successfully to differentiate the members of pseudomonad rRNA homology groups (Byng et al., 1983). The multibranched pathway of aromatic amino acid synthesis offers not only a degree of variation in biochemical details not exhibited in the pathway of aliphatic amino acid synthesis, but also a richer source of regulatory information. For these reasons, Jensen and his collaborators exploited the interconnected pathways of aromatic amino acid synthesis as a model for the study of the phylogenetic relationships

among the groups of aerobic pseudomonads (Byng et al., 1980; Byng et al., 1982; Whitaker et al., 1981). The results of this work were in overall agreement with the subdivision of *Pseudomonas* into five distinct rRNA similarity groups.

Several pathways for the degradation of arginine by different species of the genus *Pseudomonas* are known. In one of the pathways, known as the arginine dihydrolase or arginine deiminase pathway, arginine is converted to citrulline and this, in turn, into ornithine and ATP, which allows the cells to maintain their motility for an extended time under anaerobiosis (Hills, 1940; Slade et al., 1954; Sherris et al., 1959). The presence of arginine deiminase is assayed by the disappearance of arginine or, more simply, an increase in the pH of the medium, owing to ammonia liberation (Thornley, 1960).

Pathways of arginine degradation in *Pseudomonas* are further characterized by key reactions: arginine dehydrogenase (oxidase) and arginine succinyl transferase in fluorescent species, as well as in species of other pseudomonad genera (Stalon and Mercenier, 1984; Stalon et al., 1987; Jann et al., 1988). The arginine dihydrolase system may no longer be considered to be characteristic of *Pseudomonas*, since it is detected also in species of other genera, and some *Pseudomonas* species (such as *P. stutzeri*) give a negative reaction. However, analysis of arginine dihydrolase, in combination with other tests, still can be of diagnostic value.

Arginine metabolism in *Pseudomonas* species with multiple catabolic pathways for its utilization as carbon and nitrogen sources is of particular importance for the control of metabolic integration in cells. Transcriptome analyses identified genes controlled by the arginine regulatory protein ArgR in *P. aeruginosa* (Lu et al., 2004). Ten putative transcriptional units of 28 genes were observed to be inducible by ArgR and arginine, indicating that ArgR is important in the control of arginine and glutamate metabolism and that arginine and ArgR may have redundant effects in the induction of uptake systems of certain compounds.

Physiology

Metabolism and Metabolic Pathways

The metabolism of *Pseudomonas* (*sensu stricto*) is traditionally recognized to be strictly respiratory, although the arginine deiminase pathway yields energy and is termed "arginine fermentation" and a form of pyruvate fermentation may be carried out by some species. All species respire aerobically, using oxygen as the terminal electron acceptor for oxidative phosphorylation.

Some species also have a supplementary anaerobic respiratory system, working concurrently with the aerobic pathway. The supplementary pathway, which has been a determinative characteristic for some species of *Pseudomonas*, uses nitrate (NO_3) as the final electron acceptor (nitrate respiration). Denitrification via nitrate respiration is an energy-yielding catabolic process. Assimilatory denitrification of nitrate as a source of nitrogen for growth occurs through its reduction to ammonia.

The cytochromes present in the electron transport chains of some species of *Pseudomonas* have been characterized (Stanier et al., 1966), with absorption spectra detecting *a*-, *b*- and *c*-type cytochromes in most species, although some phytopathogenic species (e.g., *P. syringae*, *P. viridiflava*, *P. savastanoi*, etc.) lack the *c*-type cytochrome (Sands et al., 1967). These observations correlate with analyses of oxidase assays of *Pseudomonas* species, in which the *c*-type cytochrome is necessary for positive reactions (Jurtshuk and McQuitty, 1976).

The first step in the oxidation of many organic substrate compounds by *Pseudomonas* species is carried out by the action of oxygenases, incorporating molecular oxygen into the chemical structure of the compound. Oxygen is a requirement for these reactions. The oxygenases form a diverse class of enzymes (mono- and dioxygenases), differing in structure, specificity and mechanism, and catalyze the oxidation of an extensive number of compounds, including hydrocarbon contaminants. Within the University of Minnesota Biocatalysis-Biodegradation Database (<http://umbbd.ahc.umn.edu>), more than 30% of the total number of enzymes catalogued are oxygenases, many derived from *Pseudomonas* species (Wackett, 2003).

As mentioned previously, some species of *Pseudomonas* are able to use nitrate as an alternative electron acceptor. Nitrate respiration is dependent upon the activities of nitrate and nitrite reductases, which are induced in the presence of nitrate under anaerobic conditions and may be repressed by oxygen. Thus, levels of oxygen may play an important role in determining the success of denitrifying populations of *Pseudomonas* species in various habitats, for example, in well-aerated soils.

Additionally, a new species of *Pseudomonas* was described recently, *P. chloritidismutans*, which is able to utilize chlorate (ClO_3^-) as an alternative energy-yielding electron acceptor, in addition to oxygen (Wolterink et al., 2002). The ability to consume and oxidize nitric oxide (NO) to nitrate under oxic conditions has been observed in one *Pseudomonas* species. The mechanism of oxidation remains unclear, although it appears to be associated to detoxifi-

cation or co-oxidation rather than an energy-yielding process. Although *Pseudomonas* has been studied for more than a century, new catabolic pathways are being detected in new isolates. The tricarboxylic acid (TCA) cycle in *Pseudomonas* is central in the regulation of cell catabolism and biosynthesis in all species. Species of *Pseudomonas* tend to utilize organic acids in preference to more complex organic compounds and this, in turn, represses many inducible peripheral catabolic enzymes. All or most of *Pseudomonas* species have incomplete glycolytic pathways, lacking 6-phosphofructokinase. *Pseudomonas* species dissimilate sugars and organic acids preferentially through the Entner-Doudoroff pathway. Hexoses and related compounds are converted to glyceraldehyde-3-phosphate and pyruvate via the Entner-Doudoroff pathway and various peripheral pathways, in which 6-phosphogluconate is a key intermediate (Eisenberg et al., 1974). All genes for the pentose phosphate pathway, the TCA cycle, the glyoxylate shunt, as well as those for the oxidative and electron transport chain, are present in the genomes of the species of *Pseudomonas* whose genomes have been sequenced.

Pseudomonas species are able to use amino acids as carbon and nitrogen sources. When amino acids are present, the cell activates a specific membrane permease, which provides the transport mechanism for the amino acids to cross into the cytoplasmic space. Using amino acids as nutrient sources saves the cell energy, as the amino acids are immediately usable, requiring little or no modification to be incorporated directly into the synthesis of cell biomass.

Some defining physiological characteristics have not been critically tested in all members of the genus, and as a consequence, occasional reports of exceptional strains have been noted. Thus, nitrogen fixation has been reported to occur in *P. stutzeri*, and *P. aeruginosa* may be capable of growing anaerobically, albeit slowly, with arginine and small amounts of yeast extract.

Genetics

Almost 10% of the genes in *P. aeruginosa*, *P. putida*, *P. syringae* and *P. fluorescens* genomes encode products involved in gene regulation, which reflects the evolutionary emphasis of this genus in monitoring and responding to a large number of environmental signals. The major regulatory control in bacteria of this genus is at the level of transcription, although an increasing number of posttranscriptional control systems are also becoming evident in this genus, to fine-tune the levels of expression of certain proteins.

This section summarizes some of the features involved in the transcriptional machinery and general regulatory circuits in *Pseudomonas*.

SIGMA FACTORS IN *PSEUDOMONAS* In *Pseudomonas*, core RNA polymerase can choose among a large number of sigma factors to transcribe the extensive variety and number of genes that species of this genus possess. *Pseudomonas* has a major sigma factor, σ^{70} , that recognizes promoters controlling the expression of housekeeping genes. Domínguez-Cuevas and Marqués (2004) compiled 149 σ^{70} -dependent *Pseudomonas* promoters, in which the transcriptional start point had been determined experimentally. They found that these promoter regions are significantly richer in AT pair content (approximately 50%) than the genomes from which they are derived (33.4% to 38.4%). The pattern resembles the consensus described for *Escherichia coli*, i.e., two conserved hexamers centered at positions -10 and -35 relative to the transcription start site. The -10 element in *P. aeruginosa* is TAtAAT and slightly different from that in *P. putida* (TATAcT), whereas the -35 element in both species is TTGACC. The spacer sequence between the -10 and -35 elements has an average length of 17 bp, although a 1-bp deviation of this length occurs with some frequency.

Multiple open reading frames (ORFs) coding for putative extracytoplasmic function (ECF) sigma factors that constitute a phylogenetically and functionally distinct subgroup within the σ^{70} family have been found in the genomes of *Pseudomonas* (Martínez-Bueno et al., 2002). Among these sigma factors are RpoS (sigma-38), RpoH (sigma-32), FliA (sigma-27), AlgU (sigma-22, homologous to RpoE in *E. coli*), PvdS and others. They control several iron uptake pathways, alginate biosynthesis, expression of virulence factors, tolerance to several stresses, expression of outer-membrane porins, etc. (Venturi et al., 1995; Brinkman et al., 1999; Burger et al., 2000; Rowen and Deretic, 2000; Schnider-Keel et al., 2001; Martínez-Bueno et al., 2002; Visca et al., 2002; Beare et al., 2003). Two ECF systems have been well characterized in *P. aeruginosa*: 1) AlgU, involved in the regulation of alginate biosynthesis, conferring a mucoid phenotype (Govan and Deretic, 1996), and directing the expression of a gene encoding the major heat shock sigma factor σ (thus, it likely plays a role in global gene regulation; Schurr and Deretic, 1997) and 2) σ^{PvdS} , a sigma factor involved in the regulation of pyoverdine siderophore biosynthesis.

The σ^E ECF factor of *P. aeruginosa* is encoded by the *algU* gene, which is part of the *algU-mucA-mucB-mucC* gene cluster. σ^E activity is controlled by the membrane-localized MucA

protein, which appears to be stabilized by the periplasmic protein MucB, although the precise function of MucC is still unknown (Boucher et al., 2000). In addition to the alginate biosynthesis genes, transcriptional microarray profiles of σ^E -dependent expression in *P. aeruginosa* revealed that the following genes are part of the σ^E circuit, namely: *pfpI*, encoding a putative protease; *osmE*, encoding an osmotically inducible lipoprotein; genes encoding several membrane proteins; genes encoding metabolic proteins; and genes encoding proteins involved in adhesion and in drug resistance (e.g., efflux pumps). σ^E has also been reported in a plant growth-promoting *P. fluorescens* strain and shown to be important for tolerance to osmotic and desiccation stress, although, unlike *P. aeruginosa*, it did not play a role in protection against heat damage (Schnider-Keel et al., 2001). The σ^E -regulated promoters exhibit the following consensus sequence [(-35) GAACCT—N16/17—(-10) TctgA].

Several ECF sigma factors are involved in iron uptake, a function that appears to be crucial for the ecological fitness of all *Pseudomonas* (Martínez-Bueno et al., 2002; Venturi et al., 2004). The best characterized of these iron uptake sigma factors is PvdS, which initiates transcription of the genes required for the biosynthesis of pyoverdine (Lamont et al., 2002; Beare et al., 2003). The signaling pathway leading to σ^{PvdS} activation involves the ferri-pyoverdine outer membrane receptor, FpvA, which, upon interaction with ferric-pyoverdine, transmits a signal to the anti- σ^{PvdS} factor, FpvR, releasing the suppression of σ^{PvdS} and resulting in initiation of the transcription of pyoverdine genes and the *toxA* and *prpL* genes in *P. aeruginosa* (Lamont et al., 2002). A three-component system similar to FpvA/FpvR/ σ^{PvdS} has been found in *P. putida* KT2440. Orthologues of σ^{PvdS} have also been identified to regulate siderophore production in *P. fluorescens* (Sexton et al., 1995). The *P. aeruginosa* PvdS protein has been shown to bind to several *pvd* promoters in which a DNA sequence at the -35 region, designated the "IS box" (G/C G/C TAAAT T/A C/G), is important for proper promoter functioning through specific recognition by this sigma factor (Wilson et al., 2001).

All *Pseudomonas* genomes have an *rpoN* gene encoding the σ^{54} factor that constitutes a group of its own, with characteristics that differ greatly from the σ^{70} family (Valls et al., 2004). As in other Gram-negative bacteria, promoters of this kind typically span DNA segments of approximately 150–200 bp. The most distinctive feature of the σ^{54} -systems is the presence of sequences that are characteristic for binding of the σ^{54} -containing RNAP, the so-called "-12/-24 motifs." These

include GG and GC doublets at positions -24 and -12, respectively, instead of the typical -10 and -35 hexamers of the σ^{70} -promoters. The second major functional motif in σ^{54} -promoters is the binding site(s) for the cognate activators. These sites may be located at various distances (50–150 bp) upstream from the -12/-24 motif. In addition to the -12/-24 and the upstream activating sequence (UAS), many (though not all) promoters have an integration host factor (IHF)-binding site at the intervening region. IHF binding to DNA sharply bends the target sequence, an event that has multiple consequences. Activation of this type of promoter is mediated mainly by members of the NtrC-family of regulators (see below). A feature to highlight is that the number and functions of the gene products of the genes transcribed by σ^{54} vary tremendously among the different *Pseudomonas* strains. However, a common characteristic is that the *rpoN* mutants of *P. aeruginosa* (Totten et al., 1990) and *P. putida* (Kohler et al., 1989) lack glutamine synthetase and fail to produce urease. *P. syringae* and *P. aeruginosa rpoN* mutants are less virulent than the corresponding wildtype strains. In the case of the plant pathogen, this is because it fails to synthesize the phytotoxin coronatine, and in *P. aeruginosa*, it is because the RpoN mutant fails to synthesize a number of virulence factors (Hendrickson et al., 2001). Last but not least, *rpoN* is required for the production and assembly of the flagellum.

FAMILIES OF REGULATORS The LysR transcriptional regulator family is the largest paralogous group in *Pseudomonas* genomes, comprising more than 100 members, which is a remarkably high value for prokaryotes (normally ranging between 2 and 12) and comparable only to the situations in *Sinorhizobium meliloti* (86), *Agrobacterium tumefaciens* (75), and *Escherichia coli* strains (45–60). LysR-type regulators are associated with the regulation of many diverse functions, and play a central role in the activation of the expression of enzymes and proteins involved in aromatic metabolism, such as in protocatechuate (PcaQ) and catechol catabolism (CatR), and of other soil- and plant-related functions. AraC transcriptional regulators control processes such as carbon metabolism, stress response, and pathogenesis and, with more than 30 members, are also highly represented in the genomes of *Pseudomonas*. Members of the NtrC family that work with σ^{54} are also abundant in all *Pseudomonas* (around 25 members) and work in many different regulatory circuits (Valls et al., 2004). In *P. aeruginosa*, these regulatory circuits include the PhhR regulator for phenylalanine metabolism (Song and Jensen, 1996), and the

regulator of the *lipA* gene, encoding a powerful lipase (Jaeger et al., 1996). In different species of the genus *Pseudomonas*, a number of catabolic pathways for the metabolism of aromatic compounds, i.e., phenol, toluene/*m*-xylene, *o*-xylene and 2-hydroxybiphenyl, are under the control of σ^{54} regulators such as DmpR, XylR, TouR and HbpR (Ramos et al., 1997; Arengi et al., 2001; Jaspers et al., 2001; Shingler, 2004; Valls et al., 2004).

The genomes of *Pseudomonas* often contain a diversity of other regulatory gene families, such as repressors of the TetR and IclR family, which often regulate the expression of resistance to antibiotics, detergents and solvents. In all *Pseudomonas* genomes, members of the following families have been found: *asnC*, *gntR*, *lacI*, *luxR*, *Cro/cI*, *merR*, *marR* and *fis*.

TWO-COMPONENT PHOSPHORELAY SYSTEMS INVOLVED IN SENSING NUTRIENTS AND STARVATIONS All strains of *Pseudomonas* species contain a large number of two-component phosphorelay systems (TCSs). These systems consist of a histidine-kinase sensor and a response regulator (RR). Variations on the histidine-kinase (HK) sensor system have been reviewed recently by Filloux et al. (2004). In short, the sensor autophosphorylates in response to environmental stimuli and then transduces the signal to a response regulator, belonging to one of the above families, which is, in turn, activated upon phosphorylation. Examples of TCSs include the FleS/FleR pair that regulates motility and adhesion to mucins in *P. aeruginosa* (Richtings et al., 1995) and the PilS and its RR PilR that regulate transcription of the pilin gene *pilA* (Hobbs et al., 1993). CrbA is a classical HK which functions in unison with CrbB (Nishijyo et al., 2001) to control several specific metabolic pathways, and modulates the catabolism of various natural substrates in response to different carbon-nitrogen (C/N) ratios. Nitrogen nutrient deprivation also involves the TCS system NtrB–NtrC, while PhoR–PhoB is involved in phosphate assimilation. As proof of the complexity of iron metabolism in *Pseudomonas*, two TCSs have been shown to play an important role in iron acquisition in *P. aeruginosa*. The PfeS–PfeR pair is required for the enterobactin-inducible production of the ferric enterobactin receptor PfeA (Dean and Poole, 1993), and the PirR–PirS system is used as a second low-affinity ferri-enterobactin uptake system (Vasil and Ochsner, 1999). The GacS sensor is involved in the regulation of virulence in *P. aeruginosa* and works with the RR GacA (Reimann et al., 1997). Some relevant issues of this system are described below.

CATABOLITE REPRESSION IN *PSEUDOMONAS* When strains of *Pseudomonas* species are exposed to a mixture of potential carbon sources, they often assimilate them in an orderly fashion. In fact, most *Pseudomonas* species metabolize many organic acids or amino acids in preference to sugars, i.e., when *Pseudomonas* is confronted with succinate and glucose, the enzymes for glucose metabolism are not induced until succinate is exhausted (Collier et al., 1996). Nevertheless, glucose is known to repress the metabolism of mannitol and histidine. In contrast to other bacteria, catabolite repression is not mediated by cAMP but rather by the integration of several signals (Rojo and Dinamarca, 2004). Although the molecular basis for catabolite repression is, as yet, not well understood, evidence gathered in different laboratories points towards a series of proteins involved in signal integration. For instance, the Crc protein is involved in the repression of the genes involved in metabolism of sugar, amino acid, and nitrogenated compounds in *P. aeruginosa* and *P. putida*. Crc controls the metabolism of branched-chained amino acids and alkanes (MacGregor et al., 1996; Canosa et al., 2000; Yuste and Rojo, 2001). This protein is also said to be involved in biofilm development in *Pseudomonas* (O'Toole et al., 2000). A surprising finding is that catabolite repression of phenol metabolism (Petruschka et al., 2001) in *P. putida* strain H, and alkane metabolism in *P. putida* strain GPo1 is alleviated by the inactivation of the cytochrome *o* ubiquinol oxidase (encoded by *cyoABCDE*). Cells are believed to sense the redox state of the respiratory chains, triggering catabolite repression processes.

Sigma-54-regulated Pu and Po promoters for the metabolism of toluene and xylenes and phenol encoded by plasmid pWW0 and pVI150 (Powlowski and Shingler, 1994; Ramos et al., 1997) are also under catabolite repression. Indeed, these promoters are not expressed during the exponential growth phase in rich media in the presence of pathway substrates (Marqués et al., 1994; Cases et al., 1996; Sze et al., 1996). Both promoters respond to the alarmone (p)ppGpp, although Po is more sensitive than Pu (Sze and Shingler, 1999; Carmona et al., 2000). The level of the alarmone is low in the exponential phase and increases in the stationary phase. The Pu promoter is also down-modulated in response to glucose in a process that involves the activities of the PtsN and PtsO proteins (Cases et al., 1999; Cases et al., 2001). Inactivation of *ptsN* makes Pu unresponsive to repression by glucose, although glucose metabolism is not affected in the mutant. On the contrary, inactivation of *ptsO* inhibits Pu activity regardless of the presence of glucose (Cases et al., 2001). The

Po promoter is not significantly influenced by PtsN-mediated glucose repression (Sze et al., 1996; Sze et al., 2002).

QUORUM SENSING In many strains of *Pseudomonas* species, production of secondary metabolites, rhamnolipids, extracellular enzymes and virulence factors is controlled by a cell-cell signaling system that is generally described as "quorum sensing" (QS) or "density-dependent gene regulation" (Fuqua et al., 1994; Fuqua et al., 1996; Salmond et al., 1995; Sitnikov et al., 1995). The basis of this system is that the bacterium produces autoinducer or signal molecules such as *N*-acyl homoserine lactones (HSLs) that accumulate in the growth medium and trigger the expression of target genes when a threshold concentration is reached.

In *P. aeruginosa*, the QS circuit is composed of the *lasRI* and the *rhlRI* systems (Van Delden and Iglewski, 1998). The *lasRI* system is composed of *lasI*, the autoinducer synthase gene responsible for the synthesis of 3-oxo-C₁₂-HSL (*N*-[3-oxododecanoyl]-L-homoserine lactone), and *lasR* which encodes the transcriptional regulator LasR (Gambello and Iglewski, 1991; Passador et al., 1993; Pearson et al., 1994). The *rhlRI* system is composed of *rhlI*, the C₄-HSL (*N*-butyrylhomoserine lactone) autoinducer synthase gene, and *rhlR*, which encode the transcriptional activator RhlR (Ochsner et al., 1994a; Ochsner et al., 1994b; Latifi et al., 1995; Pearson et al., 1995; Winson et al., 1995). At low cell density, the autoinducers 3-oxo-C₁₂-HSL and C₄-HSL are synthesized at basal levels and diffuse, or are transported into the surrounding media where they become diluted; as a consequence, no gene transcription occurs (Pearson et al., 1999). With increasing cell density, the two autoinducers accumulate until their intracellular concentration reaches a threshold level. At this critical concentration, they bind to their corresponding regulatory protein (Fuqua et al., 1996). The regulator protein-autoinducer complex binds to specific DNA sequences upstream of the target genes enhancing their transcription (Stevens et al., 1994; Stevens and Greenberg, 1997). These systems, therefore, allow bacteria to communicate with each other (cell-to-cell signaling), to sense their own density (quorum sensing), and to behave in a coordinated manner, expressing specific genes as a population rather than as individual cells (Van Delden and Iglewski, 1998). The *lasRI* system regulates *lasB* expression and is required for optimal production of other extracellular virulence factors such as LasA protease and exotoxin A (Gambello et al., 1993). This system has also been shown to induce the transcription of the *xcpP* and *xcpR* genes that encode

proteins of the *P. aeruginosa* secretory pathway (Chapon et al., 1997).

The *rhlRI* system regulates the expression of the *rhlAB* operon that encodes a rhamnosyl-transferase required for rhamnolipid production (Ochsner et al., 1994a), and is involved in the optimal production of LasB elastase, LasA protease, pyocyanin, cyanide, and alkaline protease (Brint and Ohman, 1995; Latifi et al., 1995; Pearson et al., 1997; Reimmann et al., 1997).

Both QS systems are highly specific in the sense that the respective autoinducers are unable to activate the transcriptional activator protein of the other system (Latifi et al., 1995; Pearson et al., 1997). However, both quorum-sensing systems are not completely independent of each other. The LasR/3-oxo-C₁₂-HSL complex activates the expression of *rhlR* placing the *lasRI* system in a QS hierarchy above the *rhlRI* system (Latifi et al., 1996; Pesci et al., 1997).

Transcriptome analysis has shown that QS controls not only virulence in *P. aeruginosa* but also many other genes involved in basic cellular processes, such as DNA replication, RNA transcription and translation, cell division, and amino acid biosynthesis. Another set of genes under QS control are those of chemotaxis and biofilm formation (Davies et al., 1998; De Kievit et al., 2001). Rhamnolipids, which depend on the *rhlRI* system, are required for the maintenance of biofilm architecture (Davey et al., 2003). The timing of QS activation is a continuum. Some genes are activated during early growth phase, whereas others are activated during exponential growth, or even during the stationary phase. This timing is not dependent on the concentration of autoinducer but on the availability of the transcriptional regulator proteins (LasR and RhlR; Schuster et al., 2003; Vasil, 2003).

The regulation of the QS circuit itself is complex and involves several other transcriptional regulators. The *lasRI* system is regulated both positively and negatively at several levels. It has been shown to be positively controlled by the global response regulator GacA (which together with the sensor kinase GacS forms a two-component system; Reimmann et al., 1997), as well as by Vfr (a homologue of the global transcriptional regulator CRP), which is required for the transcription of *lasRI*. The RsaL inhibitor represses the transcription of *lasI*. QscR has been shown to inhibit the premature activation of *lasI* expression at low cell density (Chugani et al., 2001). Expression of the QS system is influenced by the RpoS and RpoN sigma factors, the global posttranscriptional regulator, RsmA, and the alarmone (ppGpp; Latifi et al., 1996; Whiteley et al., 2000; Pessi et al., 2001; Van Delden et al., 2001). Adding to this complexity is the finding of a *Pseudomonas* quinolone signal

(PQS) that depends on the QS circuit for its production, and which positively regulates *rhlI*, *rhlR* and *lasR* expression and induces *lasB* transcription (Pesci et al., 1999; McKnight et al., 2000; Calfee et al., 2001; Gallagher et al., 2002).

Phenazine biosynthesis is regulated by QS in *P. aureofaciens*, *P. chlororaphis* and *P. aeruginosa* (Pierson et al., 1994; Brint and Ohman, 1995; Wood and Pierson, 1996; Chin-A-Woeng et al., 2001). Expression of the phenazine biosynthetic operon in *P. aureofaciens* is controlled by PhzI and PhzR, which are members of the family of QS regulators (Wood and Pierson, 1996). Target regulatory boxes are located upstream of both the *phzI* gene and the *phz* biosynthetic operon, enabling activation of transcription in response to high concentration of the autoinducer C₆-HSL. The central importance of QS for this strain is shown by the data that phenazine production is greatly reduced in a *phzI* mutant and is restored by addition of C₆-HSL (Wood et al., 1997). GacS/GacA system regulates phenazine production (Haas et al., 2000) via transcriptional regulation of the *phzI* gene (Chancey et al., 1999). The level of *phzI* expression in a *gacA* or a *gacS* mutant is very low.

POSTTRANSCRIPTIONAL CONTROL IN *P. FLUORESCENS* In the plant-beneficial strain *P. fluorescens* CHA0, the *hcnABC* operon, which encodes hydrogen cyanide synthase, is regulated at the posttranscriptional level, and involves the translational regulatory proteins RsmA and RsmE (Blumer et al., 1999; Haas et al., 2002; Heeb et al., 2002; Haas and Keel, 2003). Evidence for this mechanism comes from measurements of the expression of transcriptional and translational studies in different genetic backgrounds. The current model proposes that GacS/GacA activates expression of target genes at the posttranscriptional level by inducing the transcription of at least two small, untranslated regulatory RNAs, termed "RsmY" and "RsmZ," which alleviate the repressive effects of RsmA (Heeb et al., 2002; Valverde et al., 2003) and of RsmE (Pessi and Haas, 2004). RsmA and RsmE seem to bind to the mRNAs of target genes blocking their translation (Blumer et al., 1999). Mutational analysis of the *hcnA* untranslated mRNA leader region suggests that about ten nucleotides surrounding the Shine–Dalgarno sequence (GGA) are the target recognized by RsmA.

Genomics

As of June 2004, the genomes of four species of *Pseudomonas* have been sequenced and analyzed (Stover et al., 2000; Nelson et al.,

2002; Buell et al., 2003). At the time of this writing, the sequence for *P. fluorescens* was not published (see http://www.sanger.ac.uk/Projects/P_fluorescens/{The Wellcome Trust: Sanger Institute Web site}). The four species (*P. aeruginosa* strain PAO1, *P. putida* strain KT2440, *P. syringae* pv. tomato strain DC3000, and *P. fluorescens* strain SBW25) are derived from distinct phylogenetic lineages within the genus and include, respectively, an important opportunistic human pathogen, a strain used as a model system for biodegradation and other biotechnological applications, an important agricultural phytopathogen, and a plant growth-promoting strain colonizing roots and leaves.

The genomes of *Pseudomonas* species have approximately 6 Mbp (*P. aeruginosa*, 6,264,403 bp; *P. putida*, 6,181,863 bp; *P. syringae*, 6,397,126 bp; and *P. fluorescens*, approximately 6,700,000 bp), and approximately 5500 putative genes have been detected. These genomes are among the largest of the bacterial genomes that have been sequenced to date and the G+C contents of these genomes are among the highest: *P. aeruginosa*, 66.6%; *P. putida*, 61.5%; *P. syringae*, 58.4%; and *P. fluorescens*, 60.0%. Interestingly, the G+C contents determined by sequencing match almost exactly the G+C contents estimated previously for these species (Palleroni, 1984).

Detailed comparisons of the genomes of the four species of *Pseudomonas* have been compiled by Jensen et al. (2004). As this chapter is devoted to nonpathogenic aspects of *Pseudomonas*, the focus will be centered on data derived from the *P. putida* genome-sequencing project (Martins dos Santos et al., 2004; also see {TIGR Comprehensive Microbial Resource}).

Pseudomonas putida is one of the best studied species of the genus, although information on genetic organization, gene transfer, metabolism and regulation, catabolic abilities, etc., is fragmented and dispersed, providing a restricted and incomplete view of the metabolic properties and capabilities that determine its lifestyle and niche specificity. The biology of *Pseudomonas* species, their metabolic versatility, behavior under varied environmental conditions, genetic variability, and interactions with other organisms and the environment can be assessed and appreciated only within the biological context in the diverse ecological niches where they reside. *P. putida* strain KT2440 is a paradigm of the metabolically versatile species and is used worldwide as a model system for genetic and physiological studies, and for the development of biotechnological applications. *P. putida* KT2440 has been certified by the Recombinant DNA Advisory Committee of the United States National Institutes of Health as the host strain of a host-vector bio-

safety (HV1) system for gene cloning (Federal Register, 1982).

GENOME FEATURES AND GENETIC PLASTICITY

The 6.2-Mb genome of *P. putida* KT2440 contains 894 paralogous gene families, which is considerably higher than that of the 6.3-Mb genome of *P. aeruginosa* strain PAO1, which has 809 putative paralogs. This large number of paralogous families, some 50% more than so far found in other large bacterial genomes is indicative of the high degree of functional versatility of *P. putida*. The most abundant of the putative genes include the LysR transcriptional regulator family with 110 members, the response regulator receiver domain with 94 members, and the ABC transporter family with 93 members. Interestingly, the 27 families represented by more than 20 members are related to proteins involved in transcription regulation (LysR, AraC, TetR, Sigma-54, etc.), transport (ABC, major facilitator family [MFS], binding-protein-dependent transport system, and porins), environmental signaling (response regulator receiver domains, histidine kinases, PAS domain S-boxes, TonB receptors, among others) or catabolism (dehydrogenases, hydrolases, transferases, oxygenases, etc.). These features reflect the emphasis in *P. putida* on powerful cellular mechanisms that enable it to thrive in diverse environments and to compete successfully with other organisms. Of the remaining putative gene families, 770 of them (86%) have 7 or fewer members, and 537 (60%) have only 3 (171) or 2 (513) members, which is similar to other large bacterial genomes. This suggests that selection for environmental versatility has favored expansion of genetic capability through the development of numerous small paralogous families, whose members encode distinct functions, rather than by increasing the number of family members (Stover et al., 2000).

The *P. putida* KT2440 genome contains other features that reflect high functional diversity. For instance, 508 ORFs were identified as putative duplications that arose after *P. putida* diverged from a common evolutionary lineage with *P. aeruginosa*, with which it shares approximately 85% of its genome (Nelson et al., 2002). As in other studies, comparison of the *P. putida* and *P. aeruginosa* genomes suggests that most lineage-specific genes are expansions of paralogous gene families. Of the duplications found in *P. putida* KT2440, 111 (21.8%) are conserved hypothetical proteins, and 110 (21.6%) are hypothetical proteins that probably relate to the unique biology of this organism. A large family of these duplications includes 22 transposase genes resembling members of the IS4 and IS110 gene families (see

below). Lineage-specific gene duplications may reveal species-specific adaptations to habitat, since they are often accompanied by functional diversification and divergence (Tettelin et al., 2001). Indeed, of the 42 transposase and maturase genes that are present in KT2440, 24 (57%) are flanked by genes involved in energy metabolism, implying an association between these mobile elements and the metabolic capabilities of *P. putida* KT2440. This association may serve to mediate enhanced horizontal transfer or altered expression of the corresponding metabolic genes, or both.

Insertion sequence (*IS*) elements are frequently associated with genes and operons encoding accessory (i.e., non-housekeeping) functions, such as catabolic enzymes and pathways (Mae and Heinaru, 1994; Wyndham et al., 1994; Tan, 1999), pathogenicity factors (Weinel et al., 2002), and protective functions against noxious agents, such as antibiotics, biocides, detergents, etc. (Wery et al., 2001). Moreover, *IS* elements mediate gene rearrangements, and facilitate the dissemination by horizontal transfer of such gene clusters among bacterial populations (Mahillon and Chandler, 1998). The *P. putida* KT2440 genome contains a large number of *IS* elements belonging to several families, although, of the previously described transposable elements from plasmids of *Pseudomonas* species, only Tn4652, which was previously shown to be responsible for inserting plasmid genes into the *P. putida* chromosome (Mae and Heinaru, 1994), could be identified within the genome sequence. The abundance and diversity of *IS* and other transposable elements in the *P. putida* KT2440 genome underscores the importance of the accessory functions of this organism and is indicative of its genetic plasticity.

Many other atypical regions, most containing mobile elements and determinants of catabolic pathways, have been identified in the *P. putida* KT2440 genome. Codon composition analysis revealed 39 regions of the genome greater than 10 kb in length that have atypical composition, the majority of which also have a G+C content that is significantly different from that of the rest of the genome (Nelson et al., 2002). Many of these regions encode bacteriophage genes, transposable elements, or determinants for proteins involved in the metabolism of aromatic compounds. In total, 90 transposon and 92 prophage determinants have been detected.

Inspection of the *P. putida* KT2440 genome reveals that a 35-bp sequence, having the structure of an imperfect palindrome, is repeated more than 800 times throughout the genome, which has not previously been reported for

prokaryotes other than those of the Enterobacteriaceae family (Aranda-Olmedo et al., 2002). More than 80% of these sequences are extragenic and have thus been designated "Repetitive Extragenic Palindromic" ("REP") sequences. Of these, 82% are situated within 100 bp (and many within 30 bp) of the end of a neighboring gene. Given the positions and distribution of REP sequences in the *P. putida* genome, Aranda-Olmedo et al. (2002) suggested that they may serve to allow DNA gyrase to bind and relax DNA when excessive supercoiling is generated, thereby playing an important role in the regulation of gene expression.

HABITAT-SPECIFIC FUNCTIONS The genome of *P. putida* KT2440 is a complex mosaic structure with numerous and varied mobile elements, exhibiting features characteristic of terrestrial, rhizosphere and aquatic bacteria and suggests that acquisition of the combination of such features has equipped *P. putida* with its ability to thrive in diverse, often inhospitable environments, either free-living or in close association with plants.

DILUTE ENVIRONMENTS. An important characteristic of bacteria adapted to nutrient-poor aquatic lifestyles is the possession of high affinity transporters for substrates and nutrients. In addition to the relatively large number of high affinity transporters (most with an unknown substrate specificity), *P. putida* KT2440 has at least two ferric siderophore-transport systems and three ABC iron transporters, as well as 18 outer membrane ferric and ferric-related siderophore-receptors, three phosphate and two sulfonate ABC transport systems (in addition to a periplasmic sulfonate protein), as well as various transporters for sulfate, nitrate, common oligo-elements, and metals. The existence of multiple transport systems for iron and phosphate is consistent with the need to overcome phosphate and iron limitation in dilute environments and the capacity of *P. putida* to deal with the diversity of micronutrients in heterogeneous terrestrial and aquatic systems.

P. putida KT2440 specifies a large number of energy-gated outer membrane channels for substrates coupled to lower affinity cytoplasmic membrane transporters, a combination related to the ability of Proteobacteria to thrive in dilute aquatic environments (Niermman et al., 2001). *P. putida* KT2440 has 29 genes that share a TonB-dependent receptor C-terminal region, whereas bacteria such as species of Enterobacteria, which inhabit nutrient-rich niches, usually will have less than 10 (*Caulobacter crescentus* strain CB15 has 46), and a large number of high affinity transporters. The large majority of these TonB-

dependent receptors seem to be associated with iron uptake.

In addition to these diverse transport systems, *P. putida* KT2440 possesses a complex repertoire of chemosensory systems for detecting and responding to environmental signals (two-component sensors, sensor histidine kinases, chemotaxis, flagellum-related genes, etc.), and 17 extracytoplasmic function (ECF) sigma factors, 13 of which are associated with subfamily protein signature. Other “environmental” bacteria also have large numbers of ECF sigma factors: *P. aeruginosa* strain PAO has 17, *C. crescentus* 13, *Mesorhizobium loti* 19, *Sinorhizobium meliloti* 11, and *Agrobacterium tumefaciens* 11, although most genomes sequenced to date have far fewer. Furthermore, like *P. aeruginosa* strain PAO1, *P. putida* KT2440 has 22 σ^{54} -dependent transcriptional regulators, which is more than what is observed in most bacterial genomes thus far sequenced, including those of plant-associated bacteria.

SOIL AND PLANT ENVIRONMENTS. Genome features associated with a soil lifestyle include a 1-acyl-*sn*-glycerol-3-phosphate-synthase that would form N-(3-hydroxy-7-*cis*-tetradecenoyl) homoserine lactone, a quorum-sensing molecule, and a large battery of stress response systems appropriate to the fluctuating and adverse environmental conditions of terrestrial habitats. These include active efflux systems for metals (arsenate, arsenite, copper, cadmium, chromate, cyanate, etc.), organic solvents (toluene), paraquat (two paralogous sets), antibiotics (e.g., penicillin) and, interestingly, the export of fusaric acid, a toxin produced by common fungal phytopathogens such as *Fusarium oxysporum* (Schnider-Keel et al., 2000), and several export systems for biopolymers and antibiotics. These characteristics underscore the potential of *P. putida* for biocontrol activity against fungal pathogens of plants. At least, one ABC efflux transporter shows similarities to ABC pumps associated with the efflux of organic solvents (Kim et al., 1998).

Interestingly, the *P. putida* KT2440 genome possesses the determinants for resistance against many heavy metals, as this capacity has not been recognized to any great extent in *Pseudomonas*. Additionally, not less than 13 putative glutathione-S-transferase genes were identified in the *P. putida* KT2440 genome. This number is similar to those in other *Pseudomonas* (i.e., *P. aeruginosa* [15] and *P. fluorescens* [10]), or in *C. crescentus* (19), *M. loti* (10) and *S. meliloti* (16), although it is much larger than those of most sequenced genomes. Glutathione-S-transferases generally act on synthetic chemicals (Vuilleumier, 2001), although these proteins are also known to play a significant role in the deg-

radation or inactivation of electrophilic compounds, such as most xenobiotics and heavy metals (Fraser et al., 2002).

A major stress factor in soils is water deprivation, and several genes (including those for flagellin, flagellar hook, two-component sensor, outer membrane protein, sugar binding proteins, peptidyl-prolyl *cis-trans* isomerases, two-component regulators, etc.) have been observed to be involved in water deprivation stress in *P. putida* KT2440. In fact, the response of *P. putida* KT2440 to water stress seems to involve the differential expression of membrane proteins, flagella related proteins, enzymes with action on membrane composition, or heat shock proteins. *P. putida* KT2440 has a large number (10) of genes coding for universal stress proteins, which is similar to that of *Halobacter* (11) and *P. aeruginosa* (8), but higher than in most other bacterial genomes sequenced thus far. Furthermore, *P. putida* KT2440 has genes for 7 cold shock proteins, similar to *P. aeruginosa* (6) and *M. loti* (7), and more than most other bacteria. *P. putida* KT2440 has determinants for 5 heat shock proteins, *M. loti* has 7, whereas *P. aeruginosa* and *C. crescentus* each have 2. *P. putida* KT2440 possesses a number of stringent starvation-related proteins (15), most of which (13) are glutathione-S-transferases (*P. aeruginosa* has 18, *M. loti* has 10, and *C. crescentus* has 19), whereas in most other genomes, the numbers of starvation-related proteins are substantially lower.

RHIZOSPHERE AND BIOFILM FITNESS *P. putida* KT2440 has been shown to be a versatile, aggressive colonizer, being able to establish itself and persist within the rhizosphere and in bulk soils at high cell densities (Molina et al., 2000). Features that contribute to rhizosphere and soil fitness include adhesion and colonization abilities, antibiotic production, resistance to (multiple) antibiotics, capability to use seed and root exudates, production and utilization of siderophores, and ability to cope with oxidative stresses.

ADHESION. *Pseudomonas putida* KT2440, other *P. putida* strains, as well as *P. fluorescens* and other *Pseudomonas* species, colonize and quickly proliferate in the rhizosphere of a number of agriculturally important plants. The *P. putida* KT2440 genome has three relatively large ORFs, encoding the largest protein in the genome (8682 amino acids), which has been demonstrated to be essential for seed colonization in *P. putida* (Espinosa-Urgel et al., 2000). The presence of an operon for the biosynthesis of cellulose (absent in *P. aeruginosa*), as in *A. tumefaciens* and in rhizobia suggests that cellulose may facilitate the

adhesion of *P. putida* KT2440 to root tissue (Mathysse et al., 1983).

Two previously uncharacterized polysaccharide biosynthesis and export gene clusters were also identified in *P. putida* KT2440. The first cluster, absent from the genome of *P. aeruginosa*, includes four putative glycosyl transferases, a putative serine *O*-acetyltransferase, and a VirK homologue, a factor essential for intercellular spreading of *Shigella*. The second cluster included, as well, four putative glycosyl transferases, two putative lipopolysaccharide core biosynthesis proteins, and a deoxy-D-manno-octulosonic-acid (KDO) transferase. Polysaccharides are likely to play a role in the attachment of *P. putida* to plant roots. Other surface polysaccharides and lipopolysaccharides and cell-envelope components, as well, are important for adhesion to plant surfaces, as shown by Sauer and Camper (2001), who detected upregulation of genes involved in the biosynthesis of exo- and lipopolysaccharides (EPS and LPS, respectively) as well as in membrane protein genes in *P. putida* following attachment.

In the *P. putida* KT2440 genome, 23 of the 24 genes for alginate biosynthesis of regulation have been identified. The omission of the gene, the fine-tuning transcriptional regulator AlgM/MucC, is likely to hamper alginate biosynthesis (Ohman et al., 1996). Previous studies suggest that alginate biosynthesis in *P. putida* may be relatively common and it cannot be ruled out that *P. putida* KT2440 is not able to produce alginate under appropriate conditions, for instance upon attachment to plants.

COLONIZATION AND DEFENSE. Effective colonization requires the specific action and coordination of certain enzymes and proteins. Gene clusters in *P. putida* KT2440, encoding several proteins specifically involved in plant-rhizosphere interactions are absent in *P. aeruginosa* PAO1, for example, a site-specific recombinase that is essential for competitive root colonization in *P. fluorescens* (Dekkers et al., 1998). Interestingly, *P. putida* KT2440 not only colonizes roots easily, but it actually senses metabolites in the neighborhood of the rhizosphere and moves quickly towards the roots (Espinosa-Urgel et al., 2002). In addition to a complex chemosensory and chemotactic machinery (Nelson et al., 2002), *P. putida* KT2440 has a type IV fimbrial biogenesis gene set, a large operon for the biosynthesis of flagella as well as the genes coding for type I pili, curli fiber, and two chaperone/usher gene clusters, all of which are likely to contribute to the attachment capacity of *P. putida* KT2440. Consistent with this, Sauer and Camper (2001) reported that various fimbrial biosynthesis and flagellar genes in *P. putida* were differentially expressed following

attachment onto surfaces. Several other studies have demonstrated the key role of motility-related proteins in the attachment and colonization of plant or inert surfaces by *P. putida* (Turnbull et al., 2001). Other proteins related to the general type II secretion pathway, such as those encoded by the genes involved in the transport and assembly of type IV pili, also have been shown to be important for adhesion of *P. putida* (Sauer et al., 2001).

The genome of *P. putida* KT2440 includes ORFs with similarities to genes for the synthesis of the lipodepsinonepeptide class phytotoxins, such as syringomycin, as well as a cluster containing genes for polyketide biosynthesis that are typically found in antibiotic-producing strains of *Pseudomonas* species. *P. aeruginosa* pyocins (bacteriocins) have been shown to have bactericidal activity towards related pseudomonads, as well as other bacteria. Note that *P. putida* KT2440 has a large number of pyocin-related genes, 24 of them orthologues to those in *P. aeruginosa* PAO1 (Nelson et al., 2002). Additionally, *P. putida* KT2440 and other *P. putida* strains are protected from other bacterial strains or a plant host by extruding toxic compounds through their many multidrug efflux systems and by synthesis of enzymes that include penicillin resistance proteins, (metallo)- β -lactamases, cardiolipin proteases, phospholipase D, endolysin, etc. In many cases, this response is surface induced (Espinosa-Urgel et al., 2000; Sauer and Camper, 2001).

P. putida KT2440 exhibits extensive transport capabilities, with approximately 350 cytoplasmic membrane transport systems, 15% more than *P. aeruginosa* PAO1. The genes encoding for these systems form approximately 12% of the whole genome. The largest family corresponds to an ABC transporter (94 paralogous members), of which a significant proportion is predicted to be devoted to amino acid uptake. This is consistent with the ability for *P. putida* KT2440 to colonize plant roots, since root exudates are rich in amino acids, and reflects its physiological emphasis on the metabolism of amino acids and their derivatives to compete successfully in the rhizosphere. *P. putida* KT2440 also has the determinants for 11 LysE family amino acid efflux transporters (*P. aeruginosa* PAO1 has only one) that, presumably, play a key role in preventing the accumulation of inhibitory levels of amino acids or their analogues into the cell. Also consistent with its ability to colonize plant roots, *P. putida* KT2440 has a predicted ABC family opine transporter (previously been described for other rhizosphere bacteria; Lyi et al., 1999) and enzymes for the metabolism of opines, suggesting that it is capable of exploiting plant-produced opines induced in the rhizosphere by other bacterial species.

Opines are amino acids found in hairy-root hyperplasia and crown-gall tumors (Dessaux et al., 1993), and are important C- and N-sources for promoting rhizosphere-associated growth of Gram-negative bacteria.

In addition to these transport systems, the genome contains the determinants for the import of sugars (e.g., glucose, ribose and fructose), organic acids (aromatic, dicarboxylic and tricarboxylic), oligopeptides, anions (taurine, phosphate, phosphonate, sulfate, sulfonate and nitrate) and cations (ammonium, magnesium, copper, zinc, nickel, cobalt, potassium, sodium, heme and iron). Interestingly, *P. putida* KT2440 has only one phosphotransferase system (PTS) sugar transporter and a PTS-like system for nitrogen. Another large (i.e., the second largest) class of transporters is that of the Major Facilitator Superfamily, for which 48 determinants were found in the genome of *P. putida* KT2440. Most of the members are predicted to be involved in the efflux of toxic compounds although, in many cases, the substrate is unknown. The same applies to another large class, the resistance-nodulation-cell division (RND) efflux transporters.

IRON UPTAKE. A major phytoprotective effect of fluorescent pseudomonads is thought to be due to the production of siderophores under iron-limiting conditions, as well as to the ability to capture iron more efficiently than do plant pathogens (O'Sullivan and O'Gara, 1992; Walsh et al., 2001). Accordingly, *P. putida* KT2440 produces a siderophore, pyoverdine, which is a complex polypeptide produced by most fluorescent species of *Pseudomonas* and is strain-specific (Meyer et al., 2002). The pyoverdine genes in *P. putida* KT2440 are clustered in three groups and the organization is similar to that in the phytoprotectant bacteria *P. fluorescens* strain SBW25 and *P. putida* strain WCS358. The main pyoverdine transcriptional activator gene, *prfI*, is located next to the pyoverdine synthetase gene and is divergently transcribed. The gene in *P. putida* KT2440 has 93% identity with *prfI* experimentally characterized in *P. putida* WCS358 (Venturi et al., 1995) and 85% identity with *pvdS*, which is involved in the regulation of various pyoverdine biosynthesis genes in *P. aeruginosa* (Visca et al., 2002). The expression of the genes for pyoverdine production and siderophore uptake in the rhizosphere is influenced by other bacteria that coexist with *P. putida* (Loper and Henkels, 1999). Consistent with this, *P. putida* KT2440 has 29 genes whose products are predicted to be TonB-dependent outer-membrane siderophore receptors, most of which are within a gene cluster involving a transmembrane sensor, an ECF σ^{70} factor, and a transcriptional regulator, as predicted by Visca et al. (2002) for various

prokaryotes. In some cases, the siderophore receptors are clustered next to a siderophore transport system or siderophore biosynthesis genes, as for pyoverdine biosynthesis. Not surprisingly, the number of siderophore receptors in *P. putida* KT2440 is similar to that in the phytoprotectant *P. fluorescens* SBW25 but much larger than that in plant pathogens *P. syringae*, *Xylella fastidiosa*, *Ralstonia solanacearum* or *Agrobacterium tumefaciens*.

OXYGEN METABOLISM. *P. putida* KT2440, similar to plant symbionts *S. meliloti* and *M. loti* and the phytoprotectant saprophyte, *P. fluorescens*, has two complete sets of cytochrome *c* oxidase of the type *cbb3*, which has a high affinity for oxygen. Plant pathogens such as *P. syringae* or *A. tumefaciens* have only one set, and *X. fastidiosa* and *R. solanacearum* have none. Additionally, both *P. putida* KT2440 and *S. meliloti* have a second (*S. meliloti* has a third) formate dehydrogenase, which are important in fermentative processes. These two observations are consistent with the need of these bacteria to survive in the low-oxygen conditions of the rhizosphere or plant nodules.

To be able to thrive in their hosts, plant-associated microorganisms (both pathogens and symbionts or mutualists) must cope with oxidative stress, which is the first line of defense by plants against intruders. Not surprisingly and similar to other plant-associated microorganisms, *P. putida* KT2440 has many genes for dealing with oxidative stresses, including superoxide dismutases, catalases, (betaine-) aldehyde dehydrogenases, etc. In some cases, the regulation of these genes is iron-dependent and coupled to that of iron-binding proteins such as bacterioferritin.

Other relevant findings in *P. putida* KT2440 are the determinants for a bacteriophytochrome photoreceptor system that, in related prokaryotes, binds biliverdin, a breakdown product of heme metabolism (Bhoo et al., 2001). Although their precise functions are not fully known, it has been suggested such bacteriophytochromes play a role in signal transduction under oxygen and iron limitation. Interestingly, in prokaryotes, these phytochromes have been found only in microorganisms whose main habitats are soils and plants, which may be indicative of a habitat-specific function.

POTENTIAL PATHOGENICITY FACTORS. In addition to the genes described above, *P. putida* KT2440 has a number of genes that have been considered to be involved in animal or plant pathogenesis. ORFs coding for *gacA*, a cognate response regulator of *gacS* (sensor kinase) and a global regulator of secondary metabolites in Gram-negative bacteria are found also in *P. putida* KT2440. These genes are

involved in the regulation of the syringomicin production in *P. syringae* and of virulence functions in *P. aeruginosa* PAO1 (Rhame et al., 2001). Also of interest is the presence of determinants for several thiol:disulfide bond-forming enzymes, of which some have been shown to be involved in pathogenesis of both human and plant pathogens (Cao et al., 2001).

P. putida KT2440 possesses two orthologues to the *htrA* serine protease family, which have been shown to be involved in oxidative stress responses in pathogenic strains of *Salmonella* and *Yersinia* species. Additionally, one ORF encodes for a *marR* family regulator similar to *rovA* of *Y. pestis* and *Y. pseudotuberculosis*, which, in these bacteria, mediates the regulation of invasion in response to environmental signals.

Membrane lipopolysaccharides (LPS), particularly the B-band of O antigen, are often associated with virulence by many pathogens, including *P. aeruginosa* (Belanger et al., 1999). *P. putida* KT2440 has a large number of genes coding for surface polysaccharides and lipopolysaccharides, including those for the synthesis of the B-band of O antigen. However, the roles of these genes in pathogenicity are questionable.

Finally, several other ORFs, which seem to encode reported pathogenic factors have been detected: 1 ankyrin domain protein, 1 hemolysin-type calcium-binding bacteriocin, 7 leucine-rich domains, 1 endoglucanase, 3 phospholipase Ds, 7 lytic transglycosylases, β -metallo-lactamases, and VGR proteins (i.e., proteins with repetitions of Val-Gly). Interestingly, in the genome of *P. putida* KT2440, 23 paralogs of the *hlyD* (hemolysin) family secretion protein are found. However, still unclear is whether these proteins are expressed or, if so, whether they are associated with pathogenesis or simply have a habitat-specific function.

CENTRAL METABOLISM Like many other pseudomonads and rhizosymbionts, *P. putida* KT2440 has an incomplete glycolytic pathway, lacking 6-phosphofructokinase, and uses a complete Entner-Doudoroff route for utilizing glucose and other hexoses. However, it does have the genes coding for a fructose-1,6-biphosphatase and for glucose-6-phosphate isomerase, which are involved in early stages of gluconeogenesis, as well as in EPS biosynthesis. Also, like *P. aeruginosa* PAO1, *P. putida* KT2440 lacks the aldose-1-epimerase and glucose-1-phosphatase. Glucose is converted to glyceraldehyde-3-phosphate and pyruvate via the Entner-Doudoroff pathway, in which 6-phosphogluconate is a key intermediate. There are two main routes for converting glucose to 6-phosphogluconate: 1) by direct oxidation of

glucose into gluconate or 2-ketogluconate, both of which are transported to the cytoplasm, converted to 6-phosphogluconate and then further oxidized in the Entner-Doudoroff pathway; and 2) transport of glucose into the cytoplasm (via a sugar ABC-transporter), followed by phosphorylation of glucose to glucose-6-phosphate and then to 6-phosphogluconate. These two routes are cooperative, with the operation of one able to compensate for the loss of the other, although one or the other prevails, depending upon the physiological conditions. The direct oxidative pathway seems to prevail under aerobic conditions or higher substrate availability, whereas the phosphorylative pathway predominates under oxygen or glucose-limited conditions (Lessie and Phibbs, 1984).

The determinant for the membrane-associated pyrroloquinoline quinone (PQQ) glucose dehydrogenase is clustered with those for a porin B and for a TonB-dependent outer membrane receptor. The gluconokinase gene is just next to that for gluconate transport. Similarly, the genes encoding 2-ketogluconate metabolism (2-ketogluconate kinase, 2-ketogluconate 6-phosphate reductase, and epimerase) are clustered with those for a 2-ketogluconate transporter and a transcriptional regulator. Interestingly, this cluster is separated from that of the membrane-associated gluconate dehydrogenase complex, whose protein products convert gluconate to 2-ketogluconate by a transposase reading in the same direction and a potential terminator.

A patchy configuration of the various clusters coding for the enzymes of the initial stages of glucose utilization and the presence of different regulators in these gene clusters suggests a complex interplay of regulatory mechanisms with various control loops. Many of these regulatory mechanisms have been experimentally elucidated in various species of *Pseudomonas* (Clarke and Ornston, 1975), although a more comprehensive view of the gene organization within a genomic context has only become possible with the genome sequence information.

As in other *Pseudomonas* species, fructose metabolism in *P. putida* KT2440 occurs via a phosphoenolpyruvate phosphotransferase system (PTS). The genes are clustered with the 1-phosphofructokinase and the fructose transport system repressor. Other PTS-like systems encode proteins participating in a phosphorylation cascade and play an essential role in the regulation of nitrogen and carbon metabolism (Reizer et al., 1999).

P. putida KT2440 has also the glutathione-dependent glyoxalase I and II genes (as well as one for a D-lactate dehydrogenase) that code for the enzymes in the catabolism of methylglyoxal

to pyruvate. Several determinants for biosynthesis and catabolism of glycogen are clustered together within the genome. The phosphoglucomutase gene is found elsewhere in the genome and forms a cluster with an outer membrane ferric siderophore receptor, a transmembrane sensor, and an ECF σ^{70} , which indicates an iron-dependent regulatory link between environmental signals and glycogen metabolism. This is consistent with sensitive control of glycogen synthesis or for glycogen degradation, depending upon changing nutritional conditions.

Additionally, scattered throughout the genome are the genes for a periplasmic β -glucosidase, as well as those for β -(1-6)-glucan synthase, β -(1,3)-glucosyl transferase, and another copy of a glucosyl hydrolase. The β -(1-6)-glucan synthase and β -(1-3)-glucosyl transferase are similar to those in *Bradyrhizobium japonicum*, where they are involved in the synthesis of β -cyclic glucan, which is thought to be important for symbiotic interactions and to play a role in hypoosmotic adaptation (Bhagwat et al., 1996). The presence of genes coding for enzymes involved in the biosynthesis and degradation of other polysaccharides suggests a tight coupling to other "metabolic modules" and suggests a dependency upon prevailing environmental conditions.

All genes for the pentose phosphate pathway, the TCA cycle, the glyoxylate shunt, as well those for the oxidative and electron transport chain, are present in the genome of *P. putida* KT2440. ATP synthesis is driven by the resulting chemiosmotic gradient and occurs via an F-type ATP synthase. Analysis of the genome suggests that nitrogen and energy are derived from the catabolism of amino acids alanine, arginine, aspartate, asparagine, glutamine, glutamate, glycine, histidine, leucine, isoleucine, methionine, phenylalanine, serine, valine, lysine, proline, and hydroxyproline, and from the metabolism of a range of carbon compounds, including acetoin, fructose, butyrate, betaine, glucose, gluconate, glutarate, glycerol, hydantoin, lactate, malate, mannose, ribose, sorbate and sucrose, among others. Growth on these compounds has been confirmed experimentally by growing *P. putida* KT2440 on minimal media supplemented with these compounds.

BIOSYNTHESIS The genes for the synthesis of all 20 amino acids have been identified in the genome of *P. putida* KT2440. The first step in methionine biosynthesis from homoserine in *P. putida* KT2440 and other species of *Pseudomonas* is catalyzed by gene products with similarities to several known and putative homoserine O-acetyltransferases (Andersen et al., 1998;

Alaminos and Ramos, 2001). The presence of homologues to methionine biosynthesis genes suggests that *P. putida* KT2440 is able to generate homocysteine from O-succinylhomoserine through transsulfuration (via cystathionine) or by direct sulfhydrylation. Conversion of homocysteine to methionine is mediated by either of the two methionine synthetases present. The pathway configuration, which combines two different pathways, renders a greater flexibility to methionine biosynthesis and is consistent with studies demonstrating that methionine metabolism plays a crucial role in plant-microbe interactions and in bacterial fitness under stressful environmental conditions (Andersen et al., 1998; Tate et al., 1999). Genome comparisons reveal that this combination of pathways is conserved in soil or plant-associated Gram-negative bacteria *P. syringae*, *P. fluorescens*, *M. loti*, *B. fungorum*, *R. solanacearum* and *R. metallidurans*) and *X. fastidiosa*.

The pathways for the synthesis of purines, pyrimidines and nucleotides are all complete in the genome of *P. putida* KT2440. *P. putida* KT2440 can synthesize and elongate fatty acids from acetate. The genes for at least two β -oxidation pathways are present. According to its genome content, *P. putida* KT2440 should be able to synthesize an extensive variety of cofactors and prosthetic groups, including biotin, folic acid, ubiquinone, pyochelin, pantothenate, coenzyme A, ubiquinone, glutathione, thioredoxin, riboflavin, flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), nicotinamide adenine dinucleotide (NAD), NAD phosphate (NADP), porphyrin, thiamine, cobalamin, pyridoxal 5'-phosphate, tetrahydrofolate, and lipoate. In most cases, the genes encoding for the enzymes involved are scattered throughout the genome and do not aggregate in gene clusters. Although *P. putida* KT2440 is not known to grow under anaerobic conditions nor to denitrify, it has several determinants characteristic of metabolism under low oxygen tension, such as two oxygen-independent coproporphyrinogen III oxidase genes, a nitrite reductase complex, and several determinants typical of fermentative metabolism such as those for D-lactate dehydrogenase, phosphotransacetylase, formaldehyde dehydrogenase, and an acetoin gene cluster.

SURFACE POLYMERS More than 330 genes were found in the genome of *P. putida* KT2440 that are presumed to encode for proteins related to surface components and the biosynthesis and degradation of key cell-surface components. Apart from being an integral part of the cell structure, cell surface components are crucial for *P. putida* in determining motility and sensing and

in resistance and promoting attachment. The genes for the murein sacculus are grouped in three clusters scattered throughout the chromosome. Interestingly, two of these clusters include a penicillin-binding protein gene. The two other penicillin-binding protein genes are, as well, clustered with lipoproteins. The murein cluster includes also a group of genes for the synthesis of lipoic acid. Cell-division protein determinants are adjacent to a peptidoglycan synthesis gene and clustered with a σ^{32} factor. These patterns are conserved in *P. aeruginosa*, *E. coli*, *C. crescentus*, *R. solanacearum* and *A. tumefaciens*, and may reflect the close link between cell division and murein sacculus biosynthesis.

The LPS layer of the outer membrane in Gram-negative bacteria consists of a hydrophobic lipid A region anchoring the molecule in the outer leaflet, an oligosaccharide core, and an O-antigen (O polysaccharide; Raetz and Whitfield, 2002). The genes for lipid A synthesis are clustered together, and include genes involved in phospholipid biosynthesis and a gene coding for an outer membrane protein of the bacterial surface antigen family. This cluster-like structure is conserved in *P. aeruginosa*, *E. coli*, *C. crescentus* and *S. meliloti*, which agrees with the general observation that the A-lipid part of the LPS is more or less conserved within the Proteobacteria, whereas the O-antigen region (the immunogenic part in pathogens) tends to be variable, even within strains of the same species (Raymond et al., 2002).

The oligosaccharide core can be divided, conceptually, into two regions: inner core (lipid A proximal) and an outer core. As in *P. aeruginosa* and *E. coli*, several of the inner core genes in *P. putida* KT2440 are clustered together in close proximity and include the determinants for the heptose kinases, the heptosyltransferases I and II, and two lipopolysaccharide core biosynthesis proteins. However, unlike *P. aeruginosa* PAO1, the 3-deoxy-D-manno-octulosonic-acid transferase gene and the ABC lipid transporter that exports lipid A and phospholipids into the outer membrane are not within this cluster but, instead, cluster together in a region containing other genes related to the LPS-EPS core biosynthesis. This cluster includes a toluene tolerance protein as well as other genes related to oligosaccharide core biosynthesis in an arrangement similar to that of *P. aeruginosa* PAO1.

The O-antigen region in strains of *P. aeruginosa* is the most variable part of the LPS and is responsible for the different immunogenic responses in eukaryotic hosts. It generally contains an A- and a B-band. Junker et al. (2001) have determined that *P. putida* KT2440 lacks the A-band, although the genes encoding proteins for its biosynthesis are within the genome. Some

of these genes, which code for various glycosyltransferases involved in the assembly of the A-band, are contained within a gene cluster that contains also the determinants for GDP-D-rhamnose biosynthesis from GDP-D-mannose and the determinants for an ABC transport system. This structure resembles in part that of *E. coli*, *Salmonella* or *P. aeruginosa* (Rochetta et al., 1998). However, this gene cluster in *P. putida* KT2440 lacks the gene encoding an essential rhamnosyl transferase and other genes that encode for proteins involved in B-band biosynthesis. Furthermore, the ABC system of *P. putida* KT2440 does not encode for the system responsible for the transport of O-repeat units, as in *P. aeruginosa* PAO1, but rather encodes for what seems to be a protein efflux system.

Adjacent to this A-band/B-band gene cluster, although reading in the opposite direction, is a cluster containing a cytidyl-CMP-*N*-acetylneuraminic acid synthetase gene next to a hydrolase of the haloacid-dehalogenase family plus two glycosyl transferases that are likely to be involved in O-antigen synthesis. Adjacent to this group is a cluster containing the genes encoding the enzymes for the synthesis of dTDP-L-rhamnose, a sugar nucleotide precursor essential for the assemblage of the A-band of the O-antigen, as well as for alginate formation (Rochetta et al., 1999). This cluster includes, as well, genes encoding a glycosyl transferase and an *O*-acetyltransferase involved in the B-band biosynthesis. Next to this gene cluster is another one that contains several genes encoding proteins possibly involved in the synthesis and transport of the A-lipid. These genes include the determinants for a mannosyl transferase, a phosphomannose isomerase, a phosphomannomutase gene, a lipopolysaccharide ABC-export system similar to the system for export of the individual and PP-linked O units (Raetz and Whitfield, 2002), a putative penicillin-binding protein (domain), a metallo- β -lactamase protein, and a β -subunit of an integration host factor. Like other plant- and soil-associated bacteria, *P. putida* KT2440 is observed to lack the pathway for transport of the O-units across the membrane. *P. aeruginosa*, on the other hand, and similar to *E. coli* and *Salmonella*, has two pathways. Possibly, these differences may account for the avirulence of *P. putida*, as compared to *P. aeruginosa*, in which the O-antigen of the various serotypes is considered an important virulence factor. The G+C content of this gene cluster (54.3%) is lower than that for the overall genome and is likely to have been acquired by gene transfer. All of these clusters with genes encoding proteins involved in the production of LPS-EPS components have a G+C content atypically low for *P. putida* and different from that of neighboring genes not involved in

biosynthesis of lipopolysaccharides. This suggests that acquisition of the LPS-EPS genes may have occurred independently, perhaps in clusters, as has been suggested for *X. campestris* (Vorhölter et al., 2001). The complete set of genes, as well as the organization of the synthesis of the O-antigen part of the LPS is different from that in *P. aeruginosa* in its various serotypes (Rocchetta et al., 1999; Raymond et al., 2002). Rather, the set of *P. putida* KT2440 resembles those in the genomes of other soil and plant associated bacteria, such as *R. solanacearum*, *X. campestris*, *M. loti* or *S. meliloti*, perhaps reflecting the common habitat and evolutionary conditions of these bacteria.

SULFUR METABOLISM The operon enabling growth on aromatic and aliphatic sulfonates is present in *P. putida* KT2440. The genome contains the genes encoding the metabolism of alkylsulfonates, alkansulfonate-thiosulfate and thiosulfate. Furthermore, it has three genes coding for proteins similar to desulfurization enzymes although it lacks DszB monooxygenase for full desulfurization (Gallardo et al., 1996). However, the two specialized pathways encoded by *asfRABC* and *atsSRBCA*, described in other *P. putida* strains (Kahnert et al., 2000), are missing.

PERIPHERAL METABOLISM Strains of *P. putida* metabolize a variety of unusual and sometimes toxic compounds, particularly chemically stable aromatic organic compounds, and are frequently the predominant microbes isolated from polluted environments. A number of the corresponding catabolic pathways, for example, those for toluene and xylenes (Worsey and Williams, 1975; Williams and Worsey, 1976), phenols (Wong et al., 1976), naphthalene (Dunn, 1973), camphor (Rheinwald, 1973), biphenyls (Starovoirov, 1985), and chloroaromatics (Reineke, 1998) tend to be encoded by transmissible, broad host range catabolic plasmids that readily transfer between bacteria, and by catabolic transposons that readily transfer within the cell from plasmids to chromosomal locations. The location of catabolic determinants on mobile elements that can move horizontally among *Pseudomonas* species and related Proteobacteria provides such bacteria with considerable evolutionary potential, in terms of the metabolic capacities they can acquire for exploiting novel nutritional opportunities (Harayama et al., 1993).

P. putida KT2440 lacks catabolic plasmids but is known to have a chromosomal pathway for the degradation of benzoate, via catechol and 3-oxoadipate. Genome sequence analysis of *P. putida* KT2440 has revealed genetic determinants for putative enzymes able to transform a

variety of other aromatic compounds. Several of these (ferulate, coniferyl- and coumaryl alcohols, aldehydes and acids, vanillate, *p*-coumarate, *p*-hydroxybenzoate and protocatechuate) are related to lignin, generated during decomposition of plant materials, and abundant in the rhizosphere. These compounds are, therefore, likely to constitute a carbon pool for rhizosphere associated microorganisms. Furthermore, these compounds have been shown to be important for signaling in gene expression between plants and some bacteria (Venturi et al., 1998). The general strategy exploited by *Pseudomonas* species for the degradation of different aromatic compounds is to modify their diverse structures to common intermediates that can be funneled into a limited number of central pathways (Dagley, 1971). In *P. putida* KT2440, for example, initial steps in the metabolism of ferulate, *p*-coumarate, mandelate and benzoate would be mediated by different enzymes (upper pathways), although all routes ultimately converge via protocatechuate (ferulate and *p*-coumarate) or catechol (mandelate and benzoate) to the common 3-oxoadipate (also known as β -ketoadipate) pathway. Interestingly, the 3-oxoadipate pathway has been found almost exclusively in soil- and plant-associated bacteria (Harwood and Parales, 1996) and is, presumably, evolved in response to the large number of phenolic compounds synthesized by plants.

Applications

Pseudomonas species are valuable agents for biotechnological applications, primarily because of the malleable genomes of the species, supporting a diverse range of metabolisms, and a propensity to accept genetic modifications. As a group, strains of various species of *Pseudomonas* are able to extract energy from a wide range of relatively inert compounds. Applications for *Pseudomonas* range from xenobiotic waste treatment and oil spill management (Timmis et al., 1994; Dejonghe et al., 2000), treatment of fossil fuels for improved quality (Bos et al., 1996; Foght et al., 1996), biocatalysis for the synthesis of various compounds (Zeyer et al., 1985; Olivera et al., 2001), and as agents of plant growth (Lugtenberg and Weger, 1992) and protection (Voisard et al., 1994; Walsh et al., 2001). Furthermore, because of the heterogeneity of the natural habitat of *Pseudomonas*, special requirements for growth and metabolic activity may not be necessary during biotechnological applications.

BIOREMEDIATION: DEGRADATION OF CHLOROAROMATICS BY PSEUDOMONAS Chlorinated hydrocarbons comprise a spectrum of compounds that are

of industrial and economic importance. The introduction of chlorine atom(s) into a hydrocarbon significantly influences its physicochemical and biochemical properties and the tendency for bioaccumulation and environmental persistence. *Pseudomonas* species are well known for their widespread occurrence in natural habitats and their ability to utilize a variety of organic compounds, including haloaromatics.

THE CHLOROCATECHOL PATHWAY OF PSEUDOMONAS SPECIES. The first observations of microorganisms degrading chloroaromatic hydrocarbons were made in the 1960s by the groups of Alexander and Evans (Bollag et al., 1968; Tiedje et al., 1969; Gaunt and Evans, 1971; Evans et al., 1981). The elucidation of a dominant degradation pathway for chloroaromatics was carried out using one of the first bacterial strains observed to be able to degrade chloroaromatics, *Pseudomonas* sp. strain B13 (Dorn et al., 1974). *Pseudomonas* sp. B13 is capable of mineralizing 3-chlorobenzoate via 3-chloro- and 4-chlorocatechol as central intermediates. Degradation is initiated by a chromosomally encoded benzoate dioxygenase, forming 3-chloro- and 5-chlorodihydrodihydroxybenzoate in a 2:1 ratio (Reineke and Knackmuss, 1978a), followed by dehydrogenation resulting in 3-chloro- and 4-chlorocatechol (Reineke and Knackmuss, 1978b). Chlorocatechols are further degraded by a specialized set of enzymes, the chlorocatechol *ortho*-cleavage pathway (Dorn and Knackmuss, 1978a; Dorn and Knackmuss, 1978b; Schmidt and Knackmuss, 1980a; Schmidt et al., 1980b; Kaschabek and Reineke, 1992). Ring-cleavage of chlorocatechol is performed by a broad specificity chlorocatechol 1,2-dioxygenase to produce the corresponding chloro-*cis*, *cis*-muconates (Tiedje et al., 1969; Dorn and Knackmuss, 1978a; Dorn and Knackmuss, 1978b; Schmidt et al., 1980b; Broderick and O'Halloran, 1991). The elimination of the chlorine substituent has been assumed to occur spontaneously after 2-chloro- and 3-chloro-*cis*, *cis*-muconate are converted by chloromuconate cycloisomerases to 5-chloro- and 4-chloromuconolactone, respectively (Schmidt and Knackmuss, 1980a). The dienelactones (*cis*-dienelactone formed from 3-chloro- and *trans*-dienelactone from 2-chloro-*cis*, *cis*-muconate) are converted by a dienelactone hydrolase into maleylacetate (Schmidt and Knackmuss, 1980a), and a maleylacetate reductase catalyzes the reduction of the double bond to form 3-oxoadipate, the common metabolite of the 3-oxoadipate and the chlorocatechol *ortho*-cleavage pathway (Kaschabek and Reineke, 1992).

The genetic background for chlorocatechol degradation in *Pseudomonas* has been elucidated using an independently isolated 3-

chlorobenzoate degrading *P. putida* strain AC858 (Chatterjee et al., 1981), and genes encoding chlorocatechol pathway enzymes were localized on a plasmid. Similarly, chlorocatechol genes were observed to be located on plasmids in various other chloroaromatic degrading isolates (Don, 1981), including *Pseudomonas* species (Van der Meer 1991). However, in the case of *Pseudomonas* sp. B13, the chlorocatechol genes were observed to be located on a 105-kb genomic island, named "the *clc* element," present in the chromosome in two separate locations (Ravatn et al., 1998). The *clc* element integrates into the 3'-end of a target glycine tRNA gene and obviously employs a phage-type integrase to achieve site-specific integrations (Ravatn et al., 1998; Van der Meer et al., 2001). With a certain frequency the element excises, resulting in a circular intermediate. In contrast to many pathogenicity islands, the *clc* element is self-transmissible to other recipient bacteria (Springael et al., 2002). The fact that chlorocatechol genes are localized on mobile genetic elements suggests that they are transferred readily and spread in the environment.

The genes encoding the chlorocatechol pathway usually form clusters, and only a few variations in the structures of the operons have been observed, in spite of the geographically distinct origins or differences in phylogenetic positions of the bacteria. Regulatory genes usually precede the structural genes and are orientated in the opposite direction. The gene products of the regulatory genes, which are members of the LysR family, act as positive regulators. 2-Chloro-*cis*, *cis*-muconate was demonstrated to be the inducer of the *clc* operon (McFall et al., 1997). However, not only is the structure of the operons of the chlorocatechol genes similar, but also isofunctional enzymes of the chlorocatechol pathway have been shown to be homologous and more similar to each other than to the corresponding enzymes of catechol pathways, indicating that the proteobacterial chlorocatechol pathways are derived from a common origin (Schlömman, 1994).

Like *Pseudomonas* sp. strain B13, various other *Pseudomonas* species have been described that degrade 3-chlorobenzoate via a chromosomally encoded benzoate dioxygenase/dehydrogenase system and chlorocatechol genes. Benzoate dioxygenase genes have been localized in *P. putida*, *P. aeruginosa* and *P. fluorescens*, and homologous genes seem to be spread among *Pseudomonas* species. In an early study, the capability to degrade benzoate was observed to be ubiquitously present in *P. aeruginosa*, *P. chlororaphis* and *P. putida*, but few *P. stutzeri* and *P. fluorescens* strains harbored that metabolic activity (Stanier et al., 1966). The substrate specificity

of benzoate dioxygenases is restricted usually to benzoate and 3-chloro-/3-methylbenzoate, as shown for chromosomally encoded enzymes from *Pseudomonas* sp. B13 (Reineke and Knackmuss, 1978a). Thus, strains, which have been obtained from enrichment cultures using 3-chlorobenzoate as the growth substrate, are usually the product of patchwork assembly, i.e., they harbor pathway segments from different origins obtained through horizontal natural gene transfer.

In contrast to benzoate dioxygenase, the toluate 1,2-dioxygenase (XylXYZ) of *P. putida* mt-2, whose natural function is the conversion of *m*- and *p*-toluate, transforms also 4-chlorobenzoate (Reineke and Knackmuss, 1978a). 4-Chlorobenzoate is a good substrate because of its structural analogy to *p*-toluate (4-methylbenzoate). Presumably, pathways evolved for the degradation of naturally occurring methyl-substituted growth substrates can often deal with substrates bearing chlorine substituents, since both substituents are of similar size.

Thus, it was reasoned that a combination of a toluate pathway with a chlorocatechol pathway should result in derivative strains capable of mineralizing 4-chlorobenzoate. *Pseudomonas* sp. B13 acquired the ability to utilize novel substrates like 4-chloro- and 3,5-dichlorobenzoate after transfer of the TOL plasmid of *P. putida* mt-2, harboring the toluate dioxygenase genes (Reineke and Knackmuss, 1979). Similarly, transfer of the *clc* element into *P. putida* strain mt-2 resulted in 4-chlorobenzoate-degrading derivatives (Reineke et al., 1982).

Additionally, various other enzyme systems, usually involved in the degradation of naturally occurring aromatics such as toluene, phenol, salicylate or aniline are rather unspecific and tolerate additional substituents on the substrate molecule. Thus, by the judicious combination of such peripheral enzyme systems and central chlorocatechol pathway segments in a suitable host organism, complete hybrid pathways have been produced for various mono- and disubstituted chloroaromatics (Pieper and Reineke, 2000), such as chlorinated benzenes (Oltmanns et al., 1988), phenols (Schwien and Schmidt, 1982), salicylates (Rubio et al., 1986), anilines (Latorre et al., 1984) and toluenes (Abril et al., 1989; Brinkmann and Reineke, 1992).

One of the best-described enzyme systems for the activation of benzene derivatives is the broad substrate specificity toluene dioxygenase of *P. putida* strain F1, which belongs to the toluene/biphenyl family of Rieske non-heme iron dioxygenases (Gibson and Parales, 2000). The enzyme system comprises an electron transport chain of ferredoxin reductase and ferredoxin,

which channels electrons from NADH onto the catalytically active oxygenase consisting of α - and β -subunits (Yeh et al., 1977), with the α -subunit being predominantly responsible for the substrate specificity (Beil et al., 1998). Toluene is oxidized to the respective *cis*-dihydrodiol (Gibson et al., 1970), which is subsequently dehydrogenated to 3-methylcatechol. This enzyme system also accepts chlorobenzene, *p*-chloro- or *p*-bromotoluene as substrates, which are oxidized to their dihydrodiols and dehydrogenated to the respective catechols (for a review of toluene dioxygenase-catalyzed conversions, see Hudlicky et al., 1999). Similarly, 1,4-dichlorobenzene degraders can easily be evolved by acquisition of chlorocatechol genes in toluene degrading strains (Oltmanns et al., 1988). Only a few microorganisms have been isolated thus far on the basis of their abilities to degrade 1,2-dichloro- (Haigler et al., 1988), 1,3-dichloro- (De Bont et al., 1986), or 1,4-dichlorobenzene (Schraa et al., 1986; Oltmanns et al., 1988). Obviously, their enzymes are adapted specifically for transformation of their respective growth substrate. *Pseudomonas* sp. strain P51, isolated on the basis of its ability to degrade 1,2,4-trichlorobenzene (Van der Meer et al., 1987), contains a broad-spectrum chlorobenzene dioxygenase capable of transforming all dichloro- and even 1,2,4-trichlorobenzene. The respective *tcb* genes (Werlen et al., 1996) are very similar to the respective *tod* genes involved in toluene degradation by F1 (e.g., 89% identity in amino acid sequence of the respective α -subunits), indicating that small changes in amino acid sequence have a significant influence on substrate specificity.

The first enzymes of the chlorobenzene degradation pathway of strain P51, the chlorobenzene dioxygenase and the *cis*-chlorobenzene dihydrodiol dehydrogenase, are encoded on a plasmid-located transposon (Werlen et al., 1996), with the chlorocatechol genes located on the same plasmid. High similarity suggested that the chlorobenzene dioxygenase and dehydrogenase originated from a toluene or benzene degradation pathway, probably by horizontal gene transfer, to form a functional chlorobenzene degradative pathway in combination with the chlorocatechol genes.

The dioxygenation of toluene is only one of five different aerobic pathways for initializing toluene degradation. The TOL plasmid pWW0 is known to encode not only the enzymes for the degradation of *m*- and *p*-toluate (see above) but the complete set of enzymes necessary for the degradation of *m*- and *p*-xylene via the respective methylbenzoates and of toluene via benzoate as intermediates (Worsey and Williams, 1975). The degree of transformation of chloro-

toluenes by xylene monooxygenase (XylMA) depends on the position of the chlorine substituent. The substrate analogs 3-chloro- and 4-chlorotoluene are transformed at high rates, whereas no or only low activities have been detected with other chlorotoluenes. Substituents in the *ortho* position impair substrate binding (Brinkmann and Reineke, 1992). Transfer of the TOL plasmid into strain B13 allowed the isolation of chlorotoluene-degrading *Pseudomonas* species (Abril et al., 1989; Brinkmann and Reineke, 1992).

Toluene monooxygenases that hydroxylate the aromatic nucleus at all three possible positions, producing 2-methyl-, 3-methyl-, or 4-methylphenol have been described (Schields et al., 1989; Whited and Gibson, 1991; Olsen et al., 1994) and include the xylene monooxygenase systems of *P. stutzeri* OX1 (Bertoni et al., 1996) and *P. mendocina* KR1 (Whited and Gibson, 1991). These enzymes belong to an evolutionarily related family of soluble di-iron hydroxylases, including also phenol hydroxylases and methane monooxygenases. The enzyme complexes consist of an electron transport system comprising a reductase (and in some cases a ferredoxin), and a catalytic effector protein (Powlowski et al., 1997). Only limited information is available on the transformation of chlorophenols formed by monooxygenation by multicomponent toluene hydroxylases.

Salicylate hydroxylase is a flavoprotein monooxygenase that catalyzes the conversion of salicylate to catechol. The enzyme was first purified from *P. putida* S1 (Yamamoto et al., 1965), and later from various other *Pseudomonas* and pseudomonad species, and cloned and sequenced from various sources (You et al., 1991; Lee et al., 1995; Bosch et al., 1999a; Jones et al., 2000), predominantly *Pseudomonas* species. Usually, salicylate hydroxylase is included in the naphthalene pathway, and the gene encoding salicylate hydroxylase is followed by genes encoding a *meta*-cleavage pathway. Different so-called "NAH" plasmids harboring those genes have been described from *Pseudomonas* strains (Cane and Williams, 1982; Yen and Gunsalus, 1982), but in contrast, *P. stutzeri* AN10 harbors chromosomally located *nah* genes (Rosselló-Mora et al., 1994). Moreover, variations in gene organization have been observed. *P. stutzeri* AN10, besides containing *nahG* encoding salicylate hydroxylase located in one transcriptional unit with the *meta*-cleavage pathway genes, contains a second gene encoding salicylate hydroxylase, *nahW*, which is situated outside, but in close proximity to, this transcriptional unit. Both, the *nahG* and *nahW* genes of *P. stutzeri* AN10 are induced and expressed upon incubation with salicylate. Such a gene organization seems to be

common in naphthalene-degrading *P. stutzeri* strains (Bosch et al., 1999b). Despite differences in gene organization and partially low similarity (NahW shares 23–25% amino acid sequence identity to other salicylate hydroxylases), most salicylate hydroxylases described thus far exhibit similar substrate ranges with significant activities against 4-chloro- and 5-chlorosalicylate, and a lower activity against 3-chlorosalicylate (Lehrbach et al., 1984; Rubio et al., 1986; Bosch et al., 1999b; Jones et al., 2000). However, recently a new group of three component salicylate 1-hydroxylases has been described, which consist of a hydroxylase component, a ferredoxin, and a ferredoxin reductase (Pinyakong et al., 2003), differing significantly in substrate specificity from previously analyzed single component salicylate 1-hydroxylases. Given the broad substrate-specificity of salicylate 1-hydroxylases, it is not astonishing that chlorosalicylate-mineralizing strains of *Pseudomonas* species could easily be obtained by combining a salicylate hydroxylase with a functioning chlorocatechol pathway (Lehrbach et al., 1984; Rubio et al., 1986). Genes similar to those encoding salicylate hydroxylase (ca. 25–30% amino acid sequence identity) have been localized in the genomes of *P. aeruginosa* strain PAO1 and *P. putida* strain KT2440, although *P. putida* strain KT2440 is reported not to grow on salicylate (Jimenez et al., 2002). Analyses have shown that only a few strains of *Pseudomonas* species are capable of mineralizing salicylate, whereas such a capability seems to be common in *Burkholderia cepacia* (Stanier et al., 1966).

OXYGENOLYTIC DEHALOGENATION Usually, dioxygenases activating the aromatic ring attack either at two unsubstituted carbon atoms, as observed for benzenetoluene dioxygenase, or at an unsubstituted and a carboxylated carbon atom, such as demonstrated by benzoatetoluene dioxygenases, giving rise to *cis*-dihydrodiols that are transformed further by dehydrogenases to give 1,2-diphenols. Some ring-activating dioxygenases can bring about the dehalogenation of haloaromatic compounds. Benzoate dioxygenase of strain B13 attacks 2-fluorobenzoate predominantly in a 1,6-fashion, giving rise to a dihydrodiol, which is rearomatized to 3-fluorocatechol. As the ring-cleavage product 2-fluoromuconate is not a substrate for proteobacterial (chloro)muconate cycloisomerases, strain B13 cannot grow on 2-fluorobenzoate. However, prolonged adaptation resulted in derivatives that grow on this substrate. Obviously, spontaneous mutants of the benzoate dioxygenase arose, which performed a 1,2-dioxygenation (Engesser et al., 1980), such that one of the *vic*-hydroxyl groups in the

cis-dihydrodiol is bound to the same carbon as the fluoro-substituent. From such an unstable *vic*-dihydrodiol, the fluoro-substituent will be spontaneously eliminated to give catechol. However, 2-chlorobenzoate cannot be used as a growth substrate by B13-derivatives, indicating that proteobacterial benzoate dioxygenases cannot accommodate such a voluminous substituent in the *ortho*-position.

Since the 1980s, bacteria capable of degrading 2-chlorobenzoate have been reported and, thus far, only *Pseudomonas* and *Burkholderia* species have been observed to possess such a capability. The isolates could be grouped into those capable of degrading 2-chlorobenzoate, such as *P. putida* strain CLB250 (Engesser and Schulte, 1989) and *P. aeruginosa* strain 2-BBZA (Higson and Focht, 1990), and those capable of degrading also 2,4-dichloro- or 2,5-dichlorobenzoate, such as *P. stutzeri* strain KS25 (Kozlovsky et al., 1993), *P. putida* strain P111 (Hernandez et al., 1991), *P. aeruginosa* strain JB2 (Hickey and Focht, 1990), and *P. aeruginosa* strain 142 (Romanov et al., 1993). All of these organisms catalyze a 1,2-dioxygenation of 2-chlorobenzoate, thereby forming catechol, whereas 4-chlorocatechol is produced by the dioxygenation of 2,4-dichloro- and 2,5-dichlorobenzoate. Inasmuch as the degradation of 4-chlorocatechol requires a chlorocatechol degradative pathway, presumably organisms capable of degrading 2-chlorobenzoate only, and those capable of degrading also 2,4-dichloro- or 2,5-dichlorobenzoate, differ by the presence of a chlorocatechol pathway. However, two distinct 2-chlorobenzoate degrading dioxygenase systems have been described. The two-component 2-halobenzoate 1,2-dioxygenases (oxygenase consisting of α - and β -subunits and a reductase) are similar (56–59% in α -subunits amino acid sequence identity) to a two-component toluate 1,2-dioxygenase and to benzoate and toluate 1,2-dioxygenases (Harayama et al., 1991; Cowles et al., 2000) and belong to the family of benzoate dioxygenases (Gibson and Parales, 2000). These 2-halobenzoate dioxygenases are characterized by their high activity against 2-chlorobenzoate (Fetzner et al. 1992; Suzuki et al., 2001) but negligible activity against 2,4-dichloro- or 2,5-dichlorobenzoate. In contrast, the 2-chlorobenzoate dioxygenase system of *P. aeruginosa* strain 142 is a three-component dioxygenase system (an oxygenase consisting of α - and β -subunits, ferredoxin and reductase; Romanov and Hausinger, 1994). Moreover, the α -subunits of 2-chlorobenzoate dioxygenases of *P. aeruginosa* strains JB2 and 142 (Tsoi et al., 1999) exhibit only 22% amino acid sequence identity with that of *B. cepacia* strain 2CBS but higher levels of sequence similarity (42%) with the

salicylate 5-hydroxylase from *Pseudomonas* sp. strain U2 (Fuenmayor et al., 1998). Thus, 2-chlorobenzoate dioxygenases are functionally similar but represent two different lineages with distinct activities.

METABOLISM OF CHLOROAROMATICS BY 3-OXOADIPATE PATHWAY ENZYMES The aerobic degradation of aromatic compounds usually involves the successive activation and modification such that they are channeled toward a few dihydroxylated intermediates, such as catechol, gentisate or protocatechuate, which are then subjected to ring cleavage. A variety of the enzyme systems capable of activating aromatic compounds are characterized by broad substrate specificities and transform chlorinated substrate analogues, often resulting in the formation of chlorinated catechols (see above). However, only a small fraction of bacteria able to transform chloroaromatics is also capable of mineralizing them, as this usually requires the chlorocatechol pathway. Chlorocatechols are regarded as environmentally important intermediates and their metabolic fate can be of environmental significance. The chromosomally encoded 3-oxoadipate pathway is one such pathway that is widely distributed in soil bacteria and fungi (Harwood and Parales, 1996).

Marked differences have recently been demonstrated between reactions catalyzed by the chlorocatechol and the 3-oxoadipate pathway enzymes. In both cases, chlorocatechols were subject to intradiol cleavage producing the corresponding *cis,cis*-muconates (Blasco et al., 1995). However, muconate and chloromuconate cycloisomerases perform distinct reactions. Whereas chloromuconate cycloisomerases catalyze a dehalogenation of 3-chloro-*cis,cis*-muconate to form *cis*-dienelactone, muconate cycloisomerases catalyze a dehalogenation and decarboxylation to form protoanemonin, a compound of high toxicity (Seegal and Holden, 1945). Protoanemonin formation was observed to be a common reaction performed by proteobacterial muconate cycloisomerases, including those from strains of *Pseudomonas* species (Vollmer et al., 1998). Protoanemonin formation (due to channeling of intermediary chlorobenzoate into the 3-oxoadipate pathway), in turn, was assumed to be the reason for the poor survival of organisms cometabolizing polychlorinated biphenyls in soil microcosms (Blasco et al., 1997). Even chloroprotoanemonin was reported to be formed from 2,4-dichloromuconate by *P. putida* muconate cycloisomerase (Kaulmann et al., 2001). Also in the case of 2-chloromuconate turnover, muconate and chloromuconate cycloisomerases were shown to catalyze different reactions. Whereas chloromuconate

cycloisomerase catalyzes dehalogenation to form *trans*-dienelactone, via 5-chloromuconolactone as an intermediate (Vollmer and Schlömann, 1995), muconate cycloisomerases catalyze cycloisomerization only, to form 2-chloro- and 5-chloromuconolactone as stable products (Vollmer et al., 1994). Only chloromuconate cycloisomerase, but not muconate cycloisomerase, catalyzes the dehalogenation of 5-chloromuconolactone (Vollmer et al., 1994; Vollmer and Schlömann, 1995). However, 5-chloromuconolactone has been shown to be a substrate of proteobacterial muconolactone isomerases (Prucha et al., 1996a; Prucha et al., 1996b) of the 3-oxoadipate pathway. Muconolactone isomerase catalyzes a dehalogenation of 5-chloromuconolactone to form predominantly *cis*-dienelactone. The proposed mechanism was via abstraction of the C4 proton followed by spontaneous chloride elimination. Like 5-chloromuconolactone, 2-chloromuconolactone also harbors a proton at C4, which can be abstracted by muconolactone isomerase, and protoanemonin was shown to be the reaction product (Skiba et al., 2002).

THE ALTERNATIVE PATHWAY OF 4-HALOCATECHOL DEGRADATION IN *PSEUDOMONAS* Muconate cycloisomerases, as described above, form protoanemonin as a toxic dead-end product (Blasco et al., 1995). Hence, transformation of 4-chlorocatechol by enzymes of the 3-oxoadipate pathway constitutes a problematic catabolic misrouting in bacterial communities (Blasco et al., 1997). No effective activity against protoanemonin has been characterized thus far, although a degradative pathway with protoanemonin as an intermediate was proposed for 4-chlorocatechol degradation by *Pseudomonas* sp. strain RW10 (Wittich et al., 1999). This organism was shown to have a 3-oxoadipate pathway but no chlorocatechol pathway, thus forming protoanemonin from 3-chloromuconate. *Pseudomonas* sp. strain MT1, the most predominant organism in a 4-membered community isolated by continuous culture enrichment on 4-chlorosalicylate as sole carbon source (Pelz et al., 1999), was similarly proposed to have a new 4-chlorocatechol degradative pathway, which was thought to involve protoanemonin as intermediate. Both strains do not express enzymes of the chlorocatechol pathway but contain a high level of a *trans*-dienelactone hydrolase when grown on chloroaromatics. This enzyme was shown to be the key enzyme of a novel 4-chlorocatechol degradative pathway operating in *Pseudomonas* sp. strain MT1 (Nikodem et al., 2003), and probably also in *Pseudomonas* sp. strain RW10. 4-Chlorocatechol was subject to ring-cleavage

by a catechol 1,2-dioxygenase to yield 3-chloromuconate. 3-Chloromuconate was transformed to protoanemonin as the dominant reaction product by muconate cycloisomerase of strain MT1. Formation of protoanemonin is obviously a dead-end product of the pathway. Even though *trans*-dienelactone hydrolase does not act on 3-chloromuconate nor on protoanemonin, the simultaneous presence of muconate cycloisomerase and *trans*-dienelactone hydrolase yields considerably smaller protoanemonin concentrations, although higher amounts of maleylacetate from 3-chloromuconate, than muconate cycloisomerase alone (Nikodem et al., 2003). It is suggested that this enzyme acts on 4-chloromuconolactone as an intermediate in the muconate cycloisomerase-catalyzed transformation of 3-chloromuconate, thus preventing protoanemonin formation in favor of maleylacetate formation. The formed maleylacetate is reduced subsequently by maleylacetate reductase. Chlorocatechol degradation in strain MT1 thus occurs by a new pathway consisting of a patchwork of reactions recognized from the 3-oxoadipate pathway (catechol 1,2-dioxygenase and muconate cycloisomerase), the chlorocatechol pathway (maleylacetate reductase), and a *trans*-dienelactone hydrolase.

ALTERNATIVE CENTRAL PATHWAYS FOR CHLORINATED 1,2-DIPHENOLIC INTERMEDIATES For quite a long time, the presence of a catechol *meta*-cleavage pathway was assumed to interfere significantly with degradation of chloroaromatics. Catechol *meta*-cleavage routes are widespread in *Pseudomonas* species and are usually involved in the degradation of methyl-substituted compounds, such as toluene or methylphenols (Bayly et al., 1966; Worsey and Williams, 1975; Zylstra et al., 1988; Schingler et al., 1992). One of the reasons for interference was assumed to be the formation of a suicide product, reactive acyl chloride, e.g., from 3-chlorocatechol by the catechol 2,3-dioxygenase of *P. putida* mt-2 (Bartels et al., 1984). The formation of acyl chloride results in irreversible inactivation of the ring cleavage enzyme. Other enzymes such as the catechol 2,3-dioxygenase of *P. putida* F1 were reported to be reversibly inactivated by 3-chlorocatechol. Inactivation has been attributed to the potential of the substrate to chelate the active site ferrous ion (Klecka and Gibson, 1981). In other cases, reversible inactivation was shown to be due to a rapid oxidation of the active site ferrous iron into its ferric form with concomitant loss of activity (Vaillancourt et al., 2002).

Recently, *P. putida* strain GJ31 was observed to degrade chlorobenzene rapidly via 3-chlorocatechol and using a *meta*-cleavage

pathway (Mars et al., 1997). In contrast to other catechol 2,3-dioxygenases, which are subject to inactivation, the chlorocatechol 2,3-dioxygenase of strain GJ31 converts 3-chlorocatechol (Kaschabek et al., 1998; Mars et al., 1999). Stoichiometric displacement of chloride during substrate turnover leads to the production of 2-hydroxymuconate, which is further converted through the *meta*-cleavage pathway.

In contrast to 3-chlorocatechol, 4-chlorocatechol is a moderate substrate for various catechol 2,3-dioxygenases (Murray et al., 1972; Bartels et al., 1984; Kitayama et al., 1996), among them catechol 2,3-dioxygenases of family I.2.A (Eltis and Bolin, 1996), which are involved in the degradation of methylaromatics by *Pseudomonas* species. Some chlorinated compounds, degraded via 4-chlorocatechol, have been postulated to be mineralized via a catechol-degrading *meta*-cleavage pathway (Janke and Fritsche, 1979; McCullar et al., 1994; Arensdorf and Focht, 1995; Hollender et al., 1997), although the manner in which the products are dechlorinated is unknown.

Protocatechuate is a central intermediate in the degradation of various carboxylated aromatic compounds. Three modes of further degradation of protocatechuate have been reported. The intradiol cleavage by a protocatechuate 3,4-dioxygenase seems to be widespread in *Pseudomonas* species (all strains of a collection of more than 100 strains of *Pseudomonas* species displayed such an activity; Stanier et al., 1966), and the locations of the respective *pca* gene clusters have been determined within the genomes of *P. aeruginosa* strain PAO1, *P. putida* strain KT2440, *P. fluorescens* strain Pfo-1, and *P. syringae* pv. tomato DC3000 (Jimenez et al., 2002). However, this pathway seems to be unsuited for the degradation of chloroprotocatechuate.

Whereas a protocatechuate 2,3-dioxygenase has so far been described only in an isolate of a *Bacillus* species (Wolgel et al., 1993), protocatechuate 4,5-dioxygenase seems to be widespread. Strains of *Delftia acidovorans*, *Comamonas testosteroni* and *Sphingomonas paucimobilis* usually exhibit such an activity (Stanier et al., 1966; Noda et al., 1990), whereas isolates of *Pseudomonas* species do not (Stanier et al., 1966).

However, genes similar to those encoding the protocatechuate 4,5-dioxygenase pathway were observed in the genome of *P. putida* strain KT2440, although the functioning of this pathway has not been proven yet (Jimenez et al., 2002). Only the protocatechuate 4,5-dioxygenase pathway has been shown to be functional for the degradation of chloroprotocatechuate, and the formation of 2-pyrone-4,6-dicarboxylate by

nucleophilic displacement of a halide ion from protocatechuates substituted with a halogen at the C5 of the nucleus was shown (Kersten et al., 1982; Kersten et al., 1985). This indicated that cyclization, entailing nucleophilic displacement of the halogen, provides an effective alternative to the enzyme suicide inactivation that occurs when a nucleophilic group of the dioxygenase undergoes acylation. Hydrolysis of the pyrone is followed by degradation through the *meta*-cleavage pathway.

THE 4-CHLOROBENZOATE HYDROLYTIC DEHALOGENATION The degradation of 4-chlorobenzoate by a pathway distinct from that involving chlorocatechol, but involving an early dehalogenation, was indicated as early as 1976 (Ruisinger et al., 1976). *Pseudomonas* sp. strain CBS3 can be regarded as the archetypal organism from which the metabolic route and the mechanism of hydrolytic dehalogenation have been elucidated in detail (Müller et al., 1984). The 4-chlorobenzoate dehalogenase system from *Pseudomonas* sp. strain CBS3 has been shown to be a three-component enzyme complex (Elsner et al., 1991; Löffler et al., 1991) and the role of each component has been clarified (Scholten et al., 1991; Savard et al., 1992). The activation of the substrate is carried out by an ATP-dependent 4-halobenzoate-coenzyme A ligase (Löffler and Müller, 1991; Chang et al., 1992). Identification of 4-chlorobenzoyl-coenzyme A, as an intermediate in the dehalogenation, is catalyzed by 4-chlorobenzoate dehalogenase from *Pseudomonas* sp. CBS3 (Löffler et al., 1992). This is followed by dehalogenation, catalyzed by a 4-halobenzoyl-CoA dehalogenase, forming 4-hydroxybenzoyl-CoA (Liang et al., 1993; Löffler et al., 1995) in a hydrolytic substitution reaction. This enzyme was reported to share ancestry with the 2-enoyl-CoA hydratase family (Babbitt et al., 1992; Xiang et al., 1999). The last step in the reaction forming 4-hydroxybenzoate is carried out by the 4-hydroxybenzoate:coenzyme A thioesterase.

The genes encoding the 4-chlorobenzoate dehalogenase system were reported to be chromosomally localized and organized in an operon in the order: *fcB* (dehalogenase), *fcA* (ligase), and *fcC* (thioesterase; Babbitt et al., 1992). The gene organization in a second 4-chlorobenzoate-degrading *Pseudomonas* sp. strain DJ-12 was similar, although, with an additional three new genes, localized between *fcA* and *C* and, supposedly, responsible for 4-chlorobenzoate transport (Chae et al., 2000).

METABOLISM OF CHLOROBIPHENYLS Among chlorinated aromatics, the degradation of bicyclic compounds such as polychlorobiphenyls (PCBs)

or chlorinated dioxins has received special attention. A number of biphenyldegrading organisms have been isolated and they are commonly capable of transforming PCB congeners. These organisms belong to Gram-negative and Gram-positive genera and include various isolates of *Pseudomonas* species, such as *P. pseudoalcaligenes* strain KF707, *P. putida* strain KF715, *P. putida* strain OU83, and catabolize biphenyl to benzoate and 2-hydroxypenta-2,4-dienoate via the so-called "upper pathway," consisting of four enzymes, i.e., biphenyl 2,3-dioxygenase (BphA), 2,3-dihydro-2,3-dihydroxybiphenyl 2,3-dehydrogenase (BphB), 2,3-dihydroxybiphenyl 1,2-dioxygenase (BphC), and 2-hydroxy-6-oxo-6-phenylhexa-2,4-dienoate hydrolase (BphD) (Boyle et al., 1992).

Biphenyl degradation genes usually are organized in gene clusters and have been localized on bacterial chromosomes (Furukawa and Miyazaki, 1986; Erikson and Mondello, 1992), plasmids (Hooper et al., 1989) and transposons (Springael et al., 1993). Organisms such as *P. putida* strain KF717 contain a *bphABCD* gene cluster. In *Burkholderia* sp. strain LB400, genes that encode enzymes involved in the transformation of the C-5 carbon released during hydrolysis of the ring-cleavage product to form benzoate and a glutathione S-transferase are located between *bphC* and *bphD* (Hofer et al., 1994). A detailed analysis of various biphenyl degrading isolates revealed that such a genetic organization is not unique to *Burkholderia* sp. strain LB400 (Bartels et al., 1999) but occurs also in *P. pseudoalcaligenes* strain KF707 and various strains of *P. agarici*, *P. oleovorans*, *P. balearica* and *P. putida*, and seems to be widespread in *Pseudomonas*.

To a significant extent, the spectrum of PCB congeners that can be transformed by an organism is determined by the specificity of the biphenyl 2,3-dioxygenase, the enzyme which catalyzes the first step in the upper pathway and which belongs to the toluene/biphenyl family of Rieske type non-heme iron dioxygenases. Studies on various biphenyl 2,3-dioxygenases have revealed considerable differences in their congener selectivity patterns, as well as their preference of the attacked ring (Erikson and Mondello, 1993; Kimura et al., 1997; McKay et al., 1997; Seeger et al., 1999; Zielinski et al., 2002). The different substrate specificities in bacterial strains were due to relatively few differences in *bphA*, the gene coding the large subunit of the terminal biphenyl dioxygenase.

Although certain PCBs may serve as substrates for biphenyl dioxygenases, PCB-degrading organisms usually do not use PCBs as an energy source but rather cometabolize the substrates. Not surprisingly, metabolites of the

upper pathway may be formed as dead-end products (Furukawa et al., 1979; Bedard and Haberl, 1990; Seeger et al., 1997). Microorganisms capable of mineralizing a subset of PCB congeners have been obtained by judicious combination of pathway segments comprising the biphenyl upper pathway, a benzoate/toluate or 2-chlorobenzoate dioxygenase system and a chlorocatechol pathway (Mokross et al., 1990; Havel and Reineke, 1991; Hickey et al., 1992; McCullar et al., 1994; Hrywna et al., 1999), usually by *in vivo* conjugative mating of appropriate strains.

TRANSFORMATION OF BIARYLETHERS Studies by Cerniglia et al. (1979) and Klecka and Gibson (Klecka and Gibson, 1979; Klecka and Gibson, 1981), using naphthalene or biphenyl-degrading strains of *Pseudomonas* or *Sphingomonas* species, indicated that dibenzo-*p*-dioxin, dibenzofuran and chlorinated derivatives were transformed into dead-end products. Analysis of bacterial degradation of dibenzofuran (Engesser et al., 1989; Fortnagel et al., 1990), carbazole (Sato et al., 1997), dibenzo-*p*-dioxin (Wittich et al., 1992), and diphenyl ether (Schmidt et al., 1992; Dehmelt et al., 1995) revealed a novel mode of dioxygenation reaction for the aromatic nucleus, termed "angular dioxygenation," in which the carbon bonded to the heteroatoms and the adjacent carbon in the aromatic ring are oxidized. Angular dioxygenation of dibenzofuran, carbazole, dibenzo-*p*-dioxin, and diphenyl ether produces chemically unstable hemiacetal-like intermediates, which are spontaneously converted to 2,2',3-trihydroxybiphenyl, 2'-amino-2,3-dihydroxybiphenyl, 2,2',3-trihydroxydiphenyl ether, and phenol plus catechol, respectively. Angular dioxygenation thus results in the cleavage of the diphenyl ether three-ring structure. The 2'-substituted 2,3-dihydroxybiphenyls that are formed are degraded further by *meta*-cleavage and hydrolysis, resulting in the formation of salicylate (from dibenzofuran; Fortnagel et al., 1990; Strubel et al., 1991), catechol (from dibenzo-*p*-dioxin; Wittich et al., 1992), or anthranilate (from carbazole; Sato et al., 1997), respectively. So far, only a few bacterial strains capable of catalyzing angular dioxygenation have been described, predominantly strains of *Pseudomonas*, *Sphingomonas* and *Terrabacter* species. The first angular dioxygenase described originated from *Sphingomonas wittichii* strain RW1 (Armengaud et al., 1998). Like dioxygenase α -subunits of angular dioxygenases from other strains of *Sphingomonas*, *Terrabacter* and *Rhodococcus* species, the α -subunit of the RW1-derived dioxygenase is closely related to the toluene/biphenyl and naphthalene families of Rieske nonheme iron oxygenases (Shepherd and

Lloyd-Jones, 1998; Kasuga et al., 2001; Iida et al., 2002).

These angular dioxygenases do not comprise a monophylogenetic group, but are derived from at least four lineages. None of these genes has been reported thus far in *Pseudomonas* species, even though some angular dioxygenase genes were reported to be located on mobile elements (Iida et al., 2002). In contrast, carbazole dioxygenases of the phthalate family are frequently observed in *Pseudomonas* species and the gene products have been observed to transform dibenzofuran and dibenzo-*p*-dioxin (Sato et al., 1997; Habe et al., 2002), as well as chlorinated derivatives (Habe et al., 2001; Habe et al., 2002).

ANAEROBIC DEGRADATION OF HALOAROMATIC COMPOUNDS The capability for denitrification under anaerobic conditions is widespread among *Pseudomonas* species. Additionally, various dehalogenating enzymes do not require oxygen and function under anaerobic conditions. The observation of *Pseudomonas* species degrading chloroaromatics under anaerobic conditions would not be surprising, and the establishment of the *Pseudomonas* sp. strain CBS3 4-chlorobenzoate dehalogenase genes in *Thauera aromatica* T1, which is capable of degrading toluene and 4-hydroxybenzoate under denitrifying conditions, resulted in a derivative mineralizing 4-chlorobenzoate anaerobically (Coschigano et al., 1994).

Under denitrifying conditions, 2-fluoro- and 3-fluoro- as well as 3-chloro- and 4-chlorobenzoate can be degraded readily (Häggblom et al., 1996; Vargas et al., 2000). Analyses have shown, however, that the ability to degrade such halobenzoates under anoxic conditions is widespread among the Proteobacteria, and various strains of *Pseudomonas* species, most closely related to *P. stutzeri* (Song et al., 2000; Vargas et al., 2000), have been isolated that are capable of degrading 2-fluoro-, and 4-fluoro- as well as 3-chlorobenzoate. Evidently, *P. stutzeri* is important for halobenzoate degradation under natural conditions. However, the mechanisms of halobenzoate degradation under denitrifying conditions have not been elucidated.

IMPORTANCE OF *PSEUDOMONAS* FOR CHLOROAROMATIC DEGRADATION IN SITU The frequent isolation of strains of *Pseudomonas* species capable of degrading chloroaromatics seems to indicate that they are of some importance for degradation under natural environmental conditions. However, various catabolic pathways for chloroaromatics are plasmid encoded, and gene transfer is known to occur under environmental

conditions. Different plasmids and mobile elements, specifically those involved in the degradation of chlorobenzoate, 2,4-dichlorophenoxyacetic acid (2,4-D) or chloroaniline, have been examined for their transfer under natural conditions, and transconjugants receiving the plasmids have been characterized. Generally, the type of species recovered might be inherent to the environment that provided the selection pressure. Selection pressures might include to the ability to survive in biofilms or to scavenge nutrients. In a detailed study on two surface horizons from an agricultural soil inoculated with a *P. putida* harboring one of two distinct catabolic plasmids, pJP4 (Don and Pemberton, 1981) or pEMT1 (Top et al., 1995), changes were observed in the overall community because of proliferation of the transconjugants (Dejonghe et al., 2000), and a detailed phylogenetic analysis of these transconjugants showed that the plasmids were preferentially acquired and expressed in soil by representatives of *Ralstonia* and *Burkholderia*. Similarly, no *Pseudomonas* species could be isolated after bioaugmentation of a sandy loam soil with pJP4 donor strains (Newby et al., 2000).

Other studies have examined collections of strains obtained from environmental samples (McGowan et al., 1998). Degradation of 2,4-D among easily cultivated organisms is more widespread among strains of *Ralstonia* and *Burkholderia* species than among *Pseudomonas* species. However, such studies are dependent upon the environment analyzed. Subsurface aquifers constitute environments that are physically, chemically and biologically different from surface soils with reduced concentrations and availabilities of oxygen, carbon and nutrients, as well as lower bacterial densities (Ghiorse and Wilson, 1988). The continuous exposure of such aquifers to chlorinated phenoxyacetic acid herbicides has been shown to result in changes in the community composition with a resulting increased abundance of *Pseudomonas* species (De Liphay et al., 2003). Though only one of 50 *Pseudomonas* species mineralized 2,4-D, an important role of *Pseudomonas* on 2,4-D metabolism in situ was suggested. Rhizosphere bacteria, such as fluorescent *Pseudomonas* species, are ecologically adapted to colonize and compete in the rhizosphere environment and it can be speculated that *Pseudomonas* constitute a significant fraction of rhizosphere-associated 2,4-D degraders.

Although *Pseudomonas* sp. strain B13 was isolated as a host of the *clc* element, in inoculation experiments into natural ecosystems, the *clc* element, like *tfd* genes, ended up in *Ralstonia* or related Betaproteobacteria, like *Comamonas* (Zhou and Tiedje, 1995; Ravatn et al., 1998; Springael et al., 2002). This was assumed to

indicate that the *clc* genes are most efficiently expressed in strains belonging to those genera rather than in fluorescent pseudomonads. However, additional factors govern the acquisition and spread of a 3-chlorobenzoate-degrading phenotype in nature. 3-Chlorobenzoate is activated by a chromosomally encoded benzoate dioxygenase and dehydrogenase by organisms harboring chlorocatechol genes. Thus, properties of the benzoate dioxygenase system of possible recipient strains can be regarded as selectivity factors (Bott and Kaplan, 2002). *Pseudomonas* species were prevalent among 3-chlorobenzoate-degrading isolates harboring a chlorocatechol *ortho*-cleavage pathway (Peel and Wyndham, 1999; Krooneman et al., 2000).

Diverse pathways capable of achieving mineralization add another layer of complexity to the degradation of chlorobenzoates. Degradation of chlorobenzoates can occur via chlorocatechol (*clc* pathway), hydrolytic dehalogenation of 4-chlorobenzoate to give 4-hydroxybenzoate (*fc* pathway; Klages and Lingens, 1980), dioxygenation of 3-chlorobenzoate to give 5-chloroprotocatechuate (Nakatsu and Wyndham, 1993), and probably via a fourth pathway with gentisate as intermediate (*gp*-pathway; Krooneman et al., 1996; Krooneman et al., 1998). The archetype of the gentisate pathway for chlorobenzoate degradation was enriched under oxygen-limiting conditions (Krooneman et al., 1996). Obviously, bacteria using this pathway possessed relatively low growth rates on 3-chlorobenzoate and benzoate, along with relatively high substrate and oxygen affinities for these compounds (Krooneman et al., 2000). This is in contrast to bacteria harboring the *clc* pathway, which seem to be characterized by high maximum specific growth rates on aromatic substrates and relatively high apparent half saturation constants. Thus, presumably, bacteria degrading chlorobenzoate via gentisate or protocatechuate might be better adapted to reduced growth rate conditions (i.e., low oxygen and low substrate concentration). Evidently, the spread of the different pathways throughout different taxa has been observed, and *Pseudomonas* species were observed to harbor *clc* genes, whereas the *gp*-pathway was dominant in *Bordetella* and *Alcaligenes* species (Krooneman et al., 2000). Evidently, such clustering is due to the general genetic and metabolic equipment of the organisms. However, gentisate dioxygenase genes were observed in different *P. aeruginosa* isolates (Hickey et al., 2001) and in the genome of *P. aeruginosa* PAO1 (Stover et al., 2000) but not in the genome of *P. putida* KT2440 (Nelson et al., 2002).

Whereas a degradative pathway of chlorobenzoate via gentisate has not been analyzed in

detail, the pathway via protocatechuate has been elucidated and the crucial chlorobenzoate dioxygenase was analyzed also at the genetic level. The host range of *cbaAB* genes for 3-chlorobenzoate 4,5-dioxygenase has been analyzed both in defined mating experiments as well as by analysis of transconjugants (Fulthorpe and Wyndham, 1991; Nakatsu et al., 1995) formed under environmental conditions. Transconjugants were predominantly Betaproteobacteria, but also some *Pseudomonas* transconjugants were observed. However, those transconjugants predominantly formed 3-chlorocatechol from 3-chlorobenzoate, indicating an active benzoate 1,2-dioxygenase was interfering with 3-chlorobenzoate 4,5-dioxygenase. Moreover, 5-chloroprotocatechuate accumulated, indicating that protocatechuate 3,4-dioxygenase cannot adequately deal with this metabolite. In contrast, mineralization of 3-chlorobenzoate was observed in organisms harboring a protocatechuate 4,5-dioxygenase, an enzyme that can dehalogenate 5-chloroprotocatechuate (Kersten et al., 1982). Thus, the host range of the *cbaAB* genes can be correlated with the distribution of the protocatechuate *meta*-ring-fission pathway (Nakatsu et al., 1995). Hosts of the *fc* genotype were, in contrast, mainly *Pseudomonas* (Peel and Wyndham, 1999), which correlates with the ability of *Pseudomonas* to mineralize 4-hydroxybenzoate.

Biotransformation

Biotransformation refers to the biocatalytic conversion of a preformed substrate into a product by a single or a few enzymatic steps. Although free or immobilized enzymes may be applied as such, cofactor-dependent reactions are performed preferentially in living cells to allow inexpensive cofactor regeneration. Several cofactor-independent enzymes are applied in industry (lipases, nitrilases, isomerases, etc.) and bulk processes are based on the stable action of such enzymes. In contrast, cofactor-dependent whole cell reactions (oxidations, reductions, etc.) still have not been applied to tap their inherent potential. A key element in terms of the economics of these processes is the susceptibility of the living cell to the substrate and other components of the reaction solution and the resulting chemical produced. With the molecular tools available, it is possible to transfer genetic information from a variety of organisms into a suitable host.

Several species of *Pseudomonas* have been shown to be good host strains for the expression of heterologous genes providing considerable potential for biotechnological exploitation. Furthermore, strains of *Pseudomonas* species are

often tolerant of, or resistant to, noxious agents present in soils, including antibiotics, disinfectants, detergents, heavy metals, and organic solvents. Several species of *Pseudomonas*, in particular *P. putida*, have been shown to be good host strains for the expression of heterologous genes (Mermod et al., 1986; Ramos et al., 1987; Cases and de Lorenzo, 1998). As a result, these bacteria are viewed as potential cell factories in a diverse range of biotechnological applications, including bioremediation of contaminated sites (Dejonghe et al., 2000), quality improvement of fossil fuels, for example by desulfurization (Galan et al., 2000), biocatalysis for the production of fine chemicals (Zeyer et al., 1985; Schmid et al., 2001), the production of bioplastics (Olivera et al., 2001), and as agents of plant growth promotion and plant pest control (Walsh et al., 2001).

Moreover, a limited number of catabolic enzymes that typically mediate chemically difficult-to-achieve reactions as a consequence of their regio- and stereoselectivity, and thus have considerable potential as biocatalysts for the production of fine chemicals, have been characterized. Some of the previously unknown catabolic enzymes revealed by genome analysis may equally have promise for industrial biotransformations, such as those for the production of epoxides, substituted catechols, enantiopure alcohols and amides and heterocyclic compounds (Zeyer et al., 1985; Wubbolts and Timmis, 1990; Faber and Franssen, 1993; Schmid et al., 2001). Additionally, identification of the genes involved in the synthesis of poly-hydroxy-(phenyl)alkanoic acids, which are currently being studied as biodegradable aromatic polymers, and their precursors, will aid the development of novel bioplastics (Gorenflo et al., 2001; Olivera et al., 2001).

BIOTRANSFORMATIONS BY SOLVENT-TOLERANT PSEUDOMONAS Owing to their versatility and particularly to their chiral and positional selectivities, enzyme-mediated processes have become increasingly important for the production of fine chemicals. Many such processes, however, require cofactor regeneration, which is the major reason for the use of whole-cells biocatalysis. A number of high-value biocatalytic conversions involve apolar substrates and products, such as aliphatic, aromatic and heterocyclic compounds (Schmid et al., 2001). Such substances are generally water-insoluble and toxic to whole cells. By using multiple-phase media, it is often possible to integrate conversion and downstream processing within a single reactor system. Therefore, solvent-tolerance of the microorganisms carrying out the conversions is essential. Unlike *E. coli* or many other microorganisms, *P. putida*

strains, such as DOT-T1 (Ramos et al., 1994) or S12 (De Bont, 1998), tolerate high concentrations of solvents with low logP values, which, coupled to their metabolic versatility, make these bacteria particularly suited for the production of fine chemicals in nonconventional media. The most critical mechanism for solvent-tolerance in these bacteria is the existence of ATP-driven specific solvent-efflux pumps that extrude the solvent and hinder its accumulation in the cell membranes. Solvent-tolerant strains of *P. putida* harbor specific mechanisms that deal with environmental stresses. They have special solvent efflux pumps, and their outer membrane has specific characteristics, including an unusual fatty acid composition. Presumably, other mechanisms (stress proteins, specific compounds overproduced, etc.) involved in tolerance remain to be elucidated. The combination of these adaptive responses not only allows the organisms to withstand solvents but also places them in a far better position to cope with chemicals that are toxic to other organisms. Many of these toxic chemicals are the desired products of industry, including aldehydes, alcohols, hydroxylated aromatics and epoxides.

Summary

This review has attempted to present an overview of *Pseudomonas* in light of much of the genotypic analyses that were initiated more than 30 years ago and that have served to provide the groundwork for proposing a taxonomic framework based upon estimations of phylogenetic relationships. Certainly, these data comprise the majority of new taxonomic information obtained since the last two compilations of *Pseudomonadaceae* and *Pseudomonas* in the last two editions of *The Prokaryotes* and play an important role in revealing the heterogeneity of *Pseudomonas* sensu lato, and in improving and stabilizing the taxonomy of *Pseudomonas* sensu stricto and other pseudomonads. The recognition of the “natural” relationships of these bacteria, in turn, should lead to better appreciation and understanding of the overall biology of *Pseudomonas* spp. As new species of *Pseudomonas* are isolated and described, the correlation of metabolic and genetic characteristics with the phylogeny and taxonomy of these organisms should shed more light on the ecological and biotechnological potential of this complex bacterial genus.

Pseudomonas aeruginosa

TIMOTHY L. YAHR AND MATTHEW R. PARSEK

The Gram-negative bacillus *Pseudomonas aeruginosa* is a remarkably adaptable organism. Endowed with a large repertoire of metabolic pathways, *P. aeruginosa* is able to adapt, survive and persist under a broad range of environmental conditions. Equipped with an equally large repertoire of pathogenic mechanisms, *P. aeruginosa* is capable of infecting eukaryotic organisms ranging from social amoeba to humans. The discussion in this chapter will highlight the metabolic and pathogenic diversity of *P. aeruginosa* and the relationship to human infection.

Cellular Biology and Basic Physiology

Pseudomonas aeruginosa was first isolated from a variety of environmental sources by Schroeter in 1872 (Palleroni, 1984). Taxonomy based on 16S rRNA sequences positions *P. aeruginosa* within the class of Gammaproteobacteria and the family Pseudomonadaceae. Like all members of this family, *P. aeruginosa* is metabolically versatile and utilizes over 80 organic compounds as energy and carbon sources (Palleroni, 1984). The organism utilizes the Entner-Doudoroff pathway instead of glycolysis to oxidize sugars including fructose, galactose, glucose and xylose, is oxidase positive, and can grow at temperatures up to 42°C (Palleroni, 1984). Though *P. aeruginosa* is classified as an obligate aerobe, some strains will grow anaerobically by denitrification. ATP can also be generated anaerobically by fermentation of arginine and pyruvate (Vander Wauven et al., 1984; Eschbach et al., 2004). One important consequence of this metabolic diversity is that *P. aeruginosa* is pervasive throughout the hospital setting and persists in respiratory equipment, sinks, tubs and weak antiseptic solutions. This characteristic undoubtedly contributes to the opportunistic nature of *P. aeruginosa* infections.

The colony morphology, pigmentation, and motility properties of *P. aeruginosa* strains can be quite heterogeneous. The prototypical colony is large and smooth with an elevated center giving it the appearance of a fried egg (Palleroni, 1984). Variants with alterations in colony mor-

phology arise during biofilm growth, following exposure to environmental and antibiotic stresses, and during chronic infections of the human airways (Sheehan et al., 1982; Haussler et al., 1999; Haussler et al., 2003; Deziel et al., 2001; Drenkard and Ausubel, 2002; Boles et al., 2004; Von Gotz et al., 2004). Many colony morphology variants also display phenotypic alterations in antibiotic resistance, motility, virulence gene expression, adherence properties, and biofilm formation. The generation of variants with diverse phenotypic properties may contribute to the persistence and pathogenic success of *P. aeruginosa*.

P. aeruginosa colonies are commonly pigmented and in fact the species designation, derived from aeruginous meaning “the color of copper rust,” reflects the characteristic blue-green color imparted on colonies by the phenazine pigment pyocyanin. Pyocyanin is a redox-active compound with multiple cytopathic effects towards mammalian cells and is a product unique to *P. aeruginosa* (Lau et al., 2004). Other common pigments include the fluorescent yellow-green siderophore pyoverdinin and the rusty-brown phenazine pyorubin (Palleroni, 1984). Another phenotype observed on solid medium is mucoidy, resulting from the overproduction of alginate. Alginate is an extracellular polysaccharide composed of polymeric L-guluronic acid and D-mannuronic acid (Evans and Linker, 1973). The mucoid phenotype is most common in isolates from the airways of cystic fibrosis (CF) patients and correlates with the onset of chronic infection. Potential roles for alginate in pathogenesis include inhibition of opsonic and nonopsonic killing, increased resistance to antibiotics, and adherence to epithelial cells (May et al., 1991). Alginate is also a matrix component of biofilms formed in the CF airways. The mucoid phenotype is rapidly lost upon passage of *P. aeruginosa* in the laboratory.

Pseudomonas aeruginosa is also versatile with respect to motility and chemotaxis. Three distinct forms of motility, swimming, twitching and swarming, allow for movement in liquid and on solid surfaces. In aqueous environments *P. aeru-*

ginosa swims by means of a single polar flagella. Movement on solid surfaces is by means of twitching and swarming, whereas twitching is powered by the sequential extension and retraction of type IV pili, while swarming requires both flagella and type IV pili (Bradley, 1980; Kohler et al., 2000; Merz et al., 2000). Chemotactic responses by swimming and twitching have been demonstrated for a wide range of chemicals. Attractants include virtually all compounds known to support *P. aeruginosa* growth (Parales et al., 2004). The attractants (and repellants) are recognized by 26 methyl-accepting chemotactic receptors. These receptors transmit signals to four clusters of chemotaxis genes to modulate swimming, twitching, and cell surface properties (Parales et al., 2004). In contrast, *Escherichia coli*, with a more limited chemotactic response, has only six chemotaxis receptors and a single cluster of chemotaxis genes. The versatility of the *P. aeruginosa* chemotactic response probably co-evolved with its diverse metabolic pathways to allow for taxis towards and degradation of potential energy sources.

Pathogenesis

Though typically found in soil and water, *P. aeruginosa* is also an opportunistic pathogen of plants, invertebrates and vertebrates (Rahme et al., 1995). Involvement in human disease was first recognized in 1882 when Gessard isolated *P. aeruginosa* from bandages discolored greenish-blue with pyocyanin (Gessard, 1984). *Pseudomonas aeruginosa* is now recognized as a common source of many community acquired and nosocomial infections. The spectrum of *P. aeruginosa* infections ranges from self-limiting folliculitis to life-threatening bacteremia. The most common infections involve the cornea, skin, urinary tract, and respiratory tract, although infections may occur in essentially all anatomical locations. *Pseudomonas aeruginosa* is a leading cause of ventilator-associated pneumonia and urinary tract infections in the intensive care unit (Torres et al., 1990; Richards et al., 1999). Individuals most susceptible to *P. aeruginosa* infection include those with immunodeficiency or epithelium compromised by CF, severe burns, ulcerations, or mechanical abrasions such as those resulting from catheterization (Richards et al., 1999). Host immunodeficiency, combined with a high incidence of antibiotic resistant strains, makes treatment of *P. aeruginosa* infections a serious medical challenge.

Pseudomonas aeruginosa infections can be classified as either acute or chronic. Acute infections, such as ventilator-associated pneumonia, are invasive, cytotoxic, and frequently result in systemic infection, septic shock, and mortality

(Parillo et al., 1990; Crouch Brewer et al., 1996). In contrast, the chronic respiratory infections associated with CF, despite heavy colonization of the sputum ($>10^8$ colony-forming units [cfu]/g), are minimally invasive, noncytotoxic, and rarely progress to systemic infection (Hoiby et al., 2001; Rajan and Saiman, 2002). These chronic infections may persist for decades and ultimately result in lung deterioration and mortality. The link between the underlying genetic defect in CF and increased susceptibility to *P. aeruginosa* infection is unclear. Specific adaptations by *P. aeruginosa* to the CF airways clearly play an important role in the development of persistence. These adaptations include adoption of a biofilm lifestyle, conversion to mucoidy, and the loss of virulence gene expression including type IV pili, flagella, exotoxins, lipopolysaccharide O-antigen, and the type III secretion system (Mahenthiralingam et al., 1994; Dacheux et al., 2001a; Feltman et al., 2001; Boles et al., 2004).

VIRULENCE TRAITS The pathogenesis of *P. aeruginosa* is often described as multifactorial since virulence cannot be attributed to a single determinant. Factors with known roles in pathogenesis include adhesins, exotoxins, proteases, hemolysins, and a type III secretion system. Despite this formidable collection of virulence factors, *P. aeruginosa* rarely infects the immunocompetent or in the absence of tissue damage. This seemingly paradoxical finding reflects the poor capacity of *P. aeruginosa* to colonize and breach intact epithelia and explains why loss of epithelial integrity, especially in combination with declined immune function, is usually a prerequisite for *P. aeruginosa* infection. Once entry is gained, however, *P. aeruginosa* infections can progress rapidly. The following discussion will focus on virulence determinants with known roles in pathogenesis.

ADHERENCE. Colonization of host tissues by *P. aeruginosa* involves both fimbrial and non-fimbrial adhesins. The best characterized of the fimbrial adhesins is the type IV pili. Composed of a helical polymer of the PilA subunit, the type IV pili localize to the cell poles and account for most of the adhesive properties of *P. aeruginosa* (Hahn, 1997). Type IV pili are thought to mediate adherence to a variety of cultured epithelial cells by binding to host cell glycoproteins and low molecular weight polypeptides (Hahn, 1997). Specific binding to cultured eukaryotic cells expressing asialoganglioside GM1 has been demonstrated for some *P. aeruginosa* strains (Saiman and Prince, 1993). *Pseudomonas aeruginosa* also has three sets of type I fimbriae assembled by the chaperoneusher pathway (Vallet et al., 2001). Fimbriae, encoded by the *cupA* gene cluster, play a role in

adherence to abiotic surfaces and in biofilm formation (Vallet et al., 2001; Vallet et al., 2004). Nonfimbrial adhesins, including lipopolysaccharide, flagella, outer membrane proteins and alginate, also contribute to *P. aeruginosa* adherence.

EXOTOXIN A. Produced by most clinical isolates, exotoxin A is the most potent of the *P. aeruginosa* exotoxins with a 50% lethal dose (LD₅₀) of 2.5 µg/kg for mice (Liu, 1966; Wick et al., 1990). Its mechanism of action is identical to that of diphtheria toxin; exotoxin A inhibits protein synthesis in eukaryotes by ADP-ribosylating elongation factor 2 (Iglewski and Kabat, 1975). Toxin-deficient mutants are attenuated for virulence in most infection models. The toxin is encoded as a single polypeptide consisting of receptor binding, membrane translocation, and ADP-ribosyltransferase domains (Allured et al., 1997; Wedekind et al., 2001). Intoxication of eukaryotic cells is complex and involves binding of the toxin to its receptor α_2 -macroglobulin, internalization into the endosome, proteolytic cleavage and disulfide bond reduction, transport to the endoplasmic reticulum, and ultimately, translocation of the ADP-ribosyltransferase domain to the cytosol (Ogata et al., 1990; Kounnas et al., 1992). Expression of exotoxin A is induced under the iron-limiting conditions encountered within the host (Hamood et al., 2004).

PROTEASES. Much of the tissue damage associated with *P. aeruginosa* infections can be attributed to the zinc-dependent metalloendopeptidases LasB (elastase), LasA, and alkaline protease. Each of these proteases has been shown to contribute to virulence in animal infection models (Nicas and Iglewski, 1985). Although the name implies specificity for elastin, elastase degrades a broad range of substrates including laminin, fibrinogen, collagen, transferrin, complement components, and immunoglobulins (Engel, 2003). Given the role of these proteins in host defense, it is not surprising that mutants lacking LasB cause less tissue damage and are less virulent in experimental infection models. The LasA protease is active against a narrow range of substrates and potentiates the action of LasB, human elastase, and other host proteases by nicking substrates (Engel, 2003). LasB and LasA are both synthesized as preproenzymes and are exported across the outer membrane by the general secretory or Xcp pathway (Thanassi and Hultgren, 2000). Similar to LasB, alkaline protease demonstrates broad specificity with preferred substrates being complement components, fibrin, fibrinogen, laminin, and interferon gamma (Moriyama and Homma, 1985; Shibuya et al., 1991). Unlike elastase, alkaline protease lacks elastolytic activity and is

secreted by a type I secretion pathway (Guzzo et al., 1991).

PHOSPHOLIPASES. *Pseudomonas aeruginosa* makes two distinct phospholipases, the hemolytic PlcH and the nonhemolytic PlcN, both of which are regulated at the transcriptional level by inorganic phosphate (Shibuya et al., 1991). PlcH and PlcN are 40% identical and share a common substrate, phosphatidylcholine, found in eukaryotic membranes and lung surfactant (Ostroff et al., 1990). PlcH also hydrolyzes sphingomyelin, while PlcN shows specificity for phosphatidylserine. PlcH is cytotoxic and inhibits the respiratory burst in neutrophils (Terada et al., 1999). Mutants lacking PlcH and PlcN are less injurious and impaired in dissemination in burn wound and pneumonia infection models (Ostroff et al., 1989; Wiener-Kronish et al., 1993; Rahme et al., 1995). Many *P. aeruginosa* exoproteins, including PlcH and PlcN, are exported across the outer membrane by the general secretory (Xcp) pathway (Lazdunski et al., 1990). Although Xcp substrates are usually translocated across the inner membrane in a Sec-dependent manner, PlcH and PlcN are translocated across the inner membrane by the twin-arginine translocation system (Voulhoux et al., 2001).

TYPE III SECRETION. Type III secretion systems are common to many Gram-negative pathogens and function in the translocation of toxins from adherent bacteria directly into eukaryotic cells. Although *P. aeruginosa* pathogenesis is multifactorial, the type III system is a major determinant of virulence. In tissue culture and invertebrate and vertebrate infection models, type III secretion mutants are significantly attenuated in cytotoxicity and virulence (Nicas and Iglewski, 1984; Sawa et al., 1999; Holder et al., 2001). In human respiratory infections, expression of the type III system is associated with a sixfold increase in the relative risk of mortality (Roy-Burman et al., 2001). The type III system may also play a role in the survival of *P. aeruginosa* in soil and water (Pukatski et al., 2002).

The type III system is used to deliver four toxins, ExoS, ExoT, ExoU, and ExoY, to eukaryotic cells (Kulich et al., 1994; Yahr et al., 1996a; Yahr et al., 1998; Finck-Barbancon et al., 1997). The toxins act in concert to inhibit phagocytosis, promote tissue destruction, and impair wound healing (Finck-Barbancon et al., 1997; Geiser et al., 2001). ExoS and ExoT are related bifunctional toxins with amino-terminal GTPase activating (GAP) and carboxy-terminal ADP-ribosyltransferase domains (Barbieri, 2000). The GAP activity stimulates the Rho, Rac and Cdc42 family of signaling GTPases resulting in rearrangement of the actin cytoskeleton and inhibi-

tion of phagocytosis (Goerhing et al., 1999). Although the GAP activities of ExoS and ExoT are virtually indistinguishable, the toxins have distinct targets for ADP-ribosylation. ExoS ADP-ribosylates members of the Ras family of heterotrimeric GTPases result in cytotoxicity, whereas ExoT ADP-ribosylates Crk proteins leading to disruption of focal adhesions and inhibition of phagocytic activity (Sun and Barbieri, 2003). The biological activities of ExoU and ExoY are not as well defined. ExoU has a patatin-like phospholipase domain with broad activity towards phospholipids and neutral lipids (Sato and Frank, 2004). The phospholipase activity of ExoU irreversibly damages cellular membranes leading to rapid necrosis in cultured mammalian cells (Phillips et al., 2003; Sato et al., 2003). ExoY is homologous to the adenyl cyclase domains of anthrax toxin and CyaA of *Bordetella pertussis* (Yahr et al., 1996a). Translocation of ExoY to eukaryotic cells leads to elevated levels of intracellular cAMP and rearrangement of the actin cytoskeleton. Interestingly, all four toxins require eukaryotic cofactors for maximal catalytic activity (Coburn et al., 1991; Yahr et al., 1998; Sato et al., 2003).

Three additional proteins secreted by the type III system (PcrV, PopB and PopD) play a role in the translocation of toxins to host cells (Vallis et al., 1999). Ring-like oligomeric structures consisting of PopB/D have been visualized by electron microscopy, and when inserted into membranes, these structures are hemolytic (Dacheux et al., 2001b; Schoehn et al., 2003). The type III toxins are thought to be translocated to host cells through a channel formed by the PopB/D oligomer. The third translocation protein PcrV is required for the membrane insertion of PopD (Goure et al., 2004). Neutralizing antibodies directed against PcrV interfere with the translocation reaction and improve survival in pneumonia and burn-wound infection models (Sawa et al., 1999). Active and passive immunization strategies using PcrV are being evaluated for the treatment of human infection.

The type III secretion system (TTSS) is expressed in response to a variety of environmental signals including low Ca^{+2} concentrations, serum, and contact with eukaryotic cell surfaces (Iglewski et al., 1975; Vallis et al., 1999). Induction by the low Ca^{+2} signal is understood best and is mediated by two distinct signaling mechanisms. Both require ExsA, a positive transcriptional activator of type III gene expression (Frank et al., 1994). The first signaling mechanism involves a membrane-associated adenylate cyclase (CyaB) that catalyzes the formation of cyclic AMP under low Ca^{+2} conditions (Wolfgang et al., 2003). The rise in intracellular cAMP activates the cAMP-dependent transcriptional

factor Vfr resulting in transcription of genes encoding the type III secretion. The second pathway coupling low Ca^{+2} to TTSS gene expression is mediated directly through the type III secretion channel. Under high Ca^{+2} conditions, the secretion channel is inactive and transcription of the TTSS is repressed (Yahr et al., 1996b; McCaw et al., 2002). Transcriptional repression under these conditions is mediated by ExsD, which functions as an anti-activator by binding to and inhibiting ExsA transcriptional activity (McCaw et al., 2002). Under low Ca^{+2} conditions, the secretion channel becomes activated and, as a consequence, transcription is derepressed. Transcriptional activation requires ExsC, which functions as an anti-anti-activator by binding to and inhibiting ExsD (Dasgupta et al., 2004). The mechanism whereby ExsC is made available for binding to ExsD under low Ca^{+2} conditions is unknown.

QUORUM SENSING. An analysis of the *P. aeruginosa* genome reveals that nearly 10% of the open reading frames identified encode regulatory functions (Stover et al., 2000). One of the better-characterized regulatory systems is the cell density-dependent, quorum sensing regulatory network that uses acyl-homoserine lactone (acyl-HSL) signals. *Pseudomonas aeruginosa* makes use of two distinct quorum sensing systems, *las* and *rhl*, to coordinate gene expression with bacterial cell density. Each system consists of an acyl-HSL synthase (LasI and RhlI; Passador et al., 1993), the respective acyl-HSL signals (*N*-[3-oxodecanoyl] homoserine lactone and *N*-butyryl homoserine; Pearson et al., 1994; Pearson et al., 1995), and the corresponding DNA binding regulatory proteins (LasR and RhlR; Gambello et al., 1993). The substrates for signal synthesis by LasI and RhlI are the common cellular metabolites, *S*-adenosyl methionine and acylated acyl carrier protein (Parsek et al., 1999). LasR and RhlR are DNA-binding regulatory proteins that harbor a C-terminal helix-turn-helix DNA binding domain. In addition to LasR and RhlR, a third response regulator has been identified, QscR (Chugani et al., 2001). QscR does not have an associated signal synthase protein, and the signal to which it responds is unclear. These regulators are thought to bind to regions of dyad symmetry upstream of target promoters, termed a “*las*-” or “*rhl*-box.”

In batch culture, the acyl-HSL signals accumulate as a function of cell density. At a critical cell density (a quorum), the acyl-HSLs reach a threshold concentration at which they bind to the cognate transcriptional regulators. Although most *P. aeruginosa* genes controlled by quorum sensing are activated, some are repressed through an unknown mechanism. Three independent DNA microarray studies identified a

common set of 77 quorum-induced genes (Hentzer et al., 2001; Schuster et al., 2003; Wagner et al., 2003). Included in this set are the genes for LasA and LasB proteases, alkaline protease, and genes required for the biosynthesis of rhamnolipids, hydrogen cyanide, and the phenazine antibiotic, pyocyanin. These studies also highlight the important point that quorum sensing responses are modulated by environmental conditions. While there were 77 core genes conserved between studies, there were numerous quorum sensing-regulated genes unique to each study, probably reflecting the different environmental conditions used to grow *P. aeruginosa*. Array studies have also revealed that there is significant overlap between the quorum-sensing regulon and genes regulated by the stationary phase sigma factor, RpoS (Schuster et al., 2004). The overlap between the quorum sensing and stationary phase regulons suggests that the cell can coordinate gene expression upon both the entry into the stationary phase of growth and high cell densities. This is not surprising since these two conditions are likely to occur together.

Quorum sensing in *P. aeruginosa* is a highly integrated regulatory cascade. The *las* system has been shown to control expression of the *rhl* system, while QscR modulates expression of the *las* system (Pesci et al., 1997; Chugani et al., 2001). Finally, a secreted quinolone signal, 2-heptyl-3-hydroxy-4-quinolone (PQS), is known to affect expression of many quorum sensing-regulated virulence factors (Pesci et al., 1999). The *las* system is required for PQS production and the *rhl* system represses PQS synthesis. In addition to the complex interplay between the *las*, *rhl* and PQS systems, there is evidence that multiple regulatory systems can modulate the quorum-sensing response. For example, the GacA-GacS two-component system, MvfR and Vfr have all been shown to influence quorum sensing (Albus et al., 1997; Reimann et al., 1997; Cao et al., 2001). The multiplicity of input signals and regulatory factors indicate that quorum sensing responses can be fine-tuned to multiple environmental inputs. Finally, and notably, most of the work discussed in this section has been performed in the laboratory strain, PAO1. An analysis of various clinical isolates has demonstrated that some strains do not possess two-functional, quorum-sensing systems (Cabrol et al., 2003). Therefore, while most *P. aeruginosa* isolates do utilize acyl-HSL-based quorum sensing, the regulatory circuitry can vary extensively even within a single species.

Many of the genes regulated by quorum sensing are known virulence factors. Indeed, quorum-sensing mutants have been shown to be avirulent in three different infection model sys-

tems. In the context of infection, quorum sensing is thought to function by allowing *P. aeruginosa* to build to a critical population density before producing quorum-sensing, regulated virulence factors. By delaying the production of virulence factors that bacteria are thought to avoid an immune response by the host, until enough bacterial cells are present to overwhelm the host. However, with *P. aeruginosa* being an opportunistic pathogen, quorum sensing also probably plays an important function for the organism in the environment.

BIOFILMS. Biofilms are commonly defined as surface-associated bacterial communities encased within a polymeric matrix. Biofilms are important in *P. aeruginosa* pathogenesis, since they form on the surfaces of medical devices such as catheters, endotracheal tubes, and contact lenses, and are thought to contribute to chronic infection in the airways of cystic fibrosis (CF) patients (Parsek and Singh, 2003). Compared to their free swimming planktonic counterparts, *P. aeruginosa* growing as biofilms possess increased resistance to antibiotics, complement- and antibody-mediated clearance mechanisms, phagocytosis, and biocides (Parsek and Singh, 2003). This inherent resistance makes biofilm infections difficult to treat and in some instances, such as the respiratory infections associated with CF, impossible to eradicate. The mechanistic basis for increased biofilm resistance to antibiotics is complex and likely reflects a combination of the following: diminished metabolic activity within the biofilm, physiological changes associated with biofilm growth that lend themselves to resistance, and poor penetration of the antibiotics (Costerton et al., 1998). Recent studies have suggested that the elevated production of cyclic glucans in biofilm communities can contribute to the antibiotic resistance by physical sequestration of the antibiotic (Mah et al., 2003).

Pseudomonas aeruginosa represents one of the paradigm organisms for the study of pure culture laboratory biofilms. Much work has focused on identifying the molecular determinants that contribute to biofilm formation and function. Complicating these analyses is the fact that biofilm development is sensitive to culturing conditions. Gene-encoded functions that influence biofilm formation under one growth condition may be dispensable under a different set of conditions; however, some generalities can be made. Surface appendages, such as flagella and pili, generally contribute to both attachment to surfaces and the development of "mature" biofilms with distinct architecture. Secreted factors and membrane proteins have also been demonstrated to affect biofilm development, as they variously influence cell surface chemistry. The genetic determinants involved in biofilm devel-

opment should be presented taken with a word of caution. Not only do growth conditions influence the biofilm maturation pattern for any given strain, but significant variation is also observed between different *P. aeruginosa* strains.

Pseudomonas aeruginosa biofilm formation is thought to proceed through a number of steps that have been identified through microscopic analysis of the biofilm communities over time. These steps include initial attachment, subsequent growth and—biofilm maturation (characterized by cells encased in an extracellular matrix), followed by detachment during which bacteria actively leave the biofilm. Flagella have been implicated in initial attachment to a surface, although certain growth conditions can circumvent this requirement. Type IV pili have also been shown to be required for initial attachment (O'Toole and Kolter, 1998). Type IV-mediated twitching motility has been shown to be important for biofilm maturation, with mutants defective in twitching motility forming biofilms that are loose and unstructured in appearance (Klausen et al., 2003). Pili-associated adhesins have also been shown to play a role in initial attachment. The *cupA* locus, which shows homology to the fimbrial usher chaperone pathway, has also been shown to be important for initial attachment and subsequent development (Vallet et al., 2001). Another determinant affecting attachment is the putative exopolysaccharide encoded by the *psl* operon in nonmucoid strains (Haussler et al., 2003; Jackson et al., 2004; Matsukawa and Greenberg, 2004). Mutations in this locus have a severe attachment-deficient phenotype. A second putative exopolysaccharide biosynthetic gene cluster, the *pel* locus (Jackson et al., 2004), has been identified as a major attachment determinant in other strains.

Several factors influence biofilm maturation. Production of the surfactant, rhamnolipid, is required for maintaining void spaces and channels in mature biofilms (Davey et al., 2003). Overproduction of secreted polysaccharides has also been implicated in the formation of mature biofilms. Mucoid strains of *P. aeruginosa* (those which overproduce alginate) form biofilms with more biomass and distinctive structure when compared to nonmucoid strains (Hentzer et al., 2001). Mucoid biofilms are also more resistant to the antibiotic tobramycin than comparable nonmucoid biofilms. On the other hand, in laboratory-grown biofilms, nonmucoid strains do not appear to use alginate as a part of the extracellular matrix. Finally, quorum sensing has been shown to control biofilm formation under certain growth conditions (Davies et al., 1998). Quorum-sensing mutants in the *las* system form biofilms that are structurally distinct from the wildtype strain. The quorum-sensing mutant biofilms are

also susceptible to the surfactant sodium dodecyl sulfate. The importance of quorum sensing in biofilm development is also dependent upon culture conditions.

Summary

Because of its clinical and environmental relevance, *P. aeruginosa* continues to be a focus of intense research. This organism is arguably the paradigm for studying both biofilm communities and acyl-HSL-based quorum sensing in the laboratory. In recent years, the sequenced *P. aeruginosa* genome and the availability of DNA microarray technology have contributed to an explosion in our knowledge regarding the basic biology of *P. aeruginosa*. The momentum *P. aeruginosa* genomics has generated should continue, revealing how the regulation of different processes is coordinated and interconnected. Genomics will also facilitate the study of complex systems as researchers explore the interactions of *P. aeruginosa* with eukaryotic hosts and in environmental contexts. One thing is sure, this remarkably versatile organism will continue to surprise us in the future.

Phytopathogenic *Pseudomonads* and Related Plant-Associated *Pseudomonads*

MILTON N. SCHROTH, DONALD C. HILDEBRAND AND NICKOLAS PANOPOULOS

Phytopathogenic pseudomonads are a very diverse group of bacteria with respect to their genetics, ecology, and the kinds of diseases they cause. They currently are grouped into approximately 25 species that could easily be placed into at least three distinct genera. Moreover, there are approximately 50 pathovars in the species *P. syringae*, most of which attack different hosts. There also are pathovars in other species. These pseudomonads are worldwide in distribution and cause diseases on most major groups of higher plants. Some of the world's most serious bacterial diseases are caused by pseudomonads, such as *Pseudomonas solanacearum*. Because of the genetic diversity of the phytopathogenic pseudomonads, disease symptomatology in plants ranges from necrotic lesions, spots, cankers, and twig dieback (blights) to hyperplasias (galls, scabs), tissue maceration (rots), and vascular infections (wilts). Some pseudomonads, for example, *P. aeruginosa* and *P. cepacia*, appear to infect both plants and animals, although more work needs to be done on the comparison of strains from both sources.

Research on the phytopathogenic pseudomonads during the 1980s has been narrowly based with greatest emphasis given to such areas as molecular biology, where support funds have been more plentiful. Consequently, considerable progress has been made on understanding the genetic and physiological bases for such characteristics as virulence and host specificity. The development of DNA probes and immunological techniques to detect strains in nature also has progressed well. On the other hand, pseudomonad taxonomy and nomenclature remain perplexing since systematics has received little attention. This is unfortunate, since the defining of taxonomic relationships provides valuable information for those who are searching for clues concerning bacterial properties that relate to pathogenesis and ecological fitness. Many of the studies on the genetics of phytopathogenic

pseudomonads in the 1980s were based on findings from previous investigations comparing the physiological and pathological differences among taxa.

Upon reviewing our previous chapter on the phytopathogenic pseudomonads in the first edition of *The Prokaryotes* (Schroth et al. 1981), it is evident that there has not been a good transfer of basic information to problem solving during this decade. The diseases in general are not better controlled today than they were ten years ago and not much more is known about the ecology of the causal agents with the exception of a few taxa, such as *P. syringae* pv. *syringae*. There also have not been any particularly new innovations on management of diseases. However, it is expected that with time, the application of new information gained in the 1980s from studying such factors as virulence and host specificity will result in the development of improved approaches to control plant diseases.

In contrast to the phytopathogenic pseudomonads, there has been great activity in studying the ecology, physiology, and genetics of nonpathogenic plant-associated pseudomonads, particularly those that colonize the spermosphere and rhizosphere (Schroth and Becker, 1990; Schroth et al., 1984; Weller, 1988). Greatest interest has been with those pseudomonads that affect plant growth through their interactions with fungal plant pathogens or by their direct effect on the roots, possibly because of hormone production. Some mention is given to these microorganisms in this chapter because they colonize plant parts and in some cases appear to damage the plant. Furthermore, there is no clear demarcation between parasitism and saprophytism.

An Overview of Systematics

The evidence suggesting that the *Pseudomonas* phytopathogens belong to at least three different genera comes from various sources including rRNA-DNA homologies (Byng et al., 1983; De

Vos et al., 1985; Palleroni et al., 1973), cellular fatty acid composition and the quinone system (Oyaizu and Komagata, 1983), and enzymological patterning (Byng et al., 1983; Whitaker et al., 1981) (see also 160 and 161). The three groups containing plant pathogens are the *P. fluorescens* group (called the “fluorescents” because most form water-soluble pigments that fluoresce in visible and ultraviolet light), the *P. solanacearum*—*P. cepacia* group, and the *P. avenae* group. The latter two have been lumped together in this article as the “nonfluorescents.”

Initial assignment of plant pathogens to the nonfluorescent group is usually based not on absence of fluorescent but upon the accumulation of poly- β -hydroxybutyrate (PHB) as a storage reserve material; the nonfluorescents usually accumulate this polymer whereas the fluorescents do not. The reliability of PHB accumulation for distinguishing the nonfluorescents from fluorescents is illustrated by the example of *P. pseudoalcaligenes* subsp. *citrulli*. This phytopathogen accumulates PHB but nevertheless had been classified on the basis of some other properties as a subspecies of *P. pseudoalcaligenes* (Schaad et al., 1978), one of the few nonfluorescent species that belong to the fluorescent group. More recently, however, this pathogen has been reassigned to the *P. avenae* nonfluorescent, PHB-positive group on the basis of rRNA cistron similarities (De Vos et al., 1985). It is likely that *P. pseudoalcaligenes* subsp. *konjaci* also belongs in this group.

The title-role trait of production of water-soluble fluorescent pigments on King's medium B (King et al., 1954) is less reliable than PHB accumulation for assignment to a group. Although most members of the fluorescent group produce fluorescent pigments, exceptions exist, such as *P. agarici*, *P. corrugata*, *P. syringae* pv. *cannabina*, and *P. s.* pv. *sesami*. Others do not produce fluorescent pigments on King's medium B but do so on other media; some strains of normally fluorescent pigment-producing pathovars may be nonfluorescent (Hildebrand and Schroth, 1972). Fluorescent pigment production in some instances can be induced by iron-chelating techniques (Garibaldi, 1967) or by use of media other than King's medium B, such as that described for *P. s.* pv. *persicae* by Luisetti et al. (1972). Certain members of the nonfluorescent groups, such as *P. cepacia* and *P. gladioli*, produce diffusible yellow pigments similar in appearance to fluorescent pigments except that they do not fluoresce. Consequently, pigments must be examined under ultraviolet light (Hildebrand et al., 1973). Other properties such as utilization of cellobiose and D-arabinose can be used to identify many of the nonfluorescent pseudomonads.

The Fluorescent Group of Phytopathogenic *Pseudomonads*

The taxonomy of the fluorescent group of phytopathogenic pseudomonads has been debated for years. Many of the original species were named primarily on the basis of the host plant from which the pathogen was isolated and its presumed host range, not on a comparative phenotypic characterization. The problem of inadequate characterization has remained with us. Few species of phytopathogenic pseudomonads were included in the 1980 *Approved Lists of Bacterial Names* (Skerman et al., 1980) because of inadequate characterization. The only names of phytopathogenic species and subspecies of the fluorescent group which appear in the 1980 *Approved Lists* and the 1985 update (Moore et al., 1985) are *P. agarici*, *P. amygdali*, *P. caricapapayae*, *P. cichorii*, *P. coronafaciens*, *P. corrugata*, *P. fuscovaginae*, *P. marginalis*, *P. meliae*, *P. syringae*, *P. syringae* subsp. *savastanoi*, *P. tolaasi*, and *P. viridiflava*. Because of the problem of inadequate characterization, a scheme was developed which designated the many distinct pathogens as pathovars of several recognized species, primarily *P. syringae*. This was adopted as an interim expedient; accordingly, a list of pathovars and related information was published (Dye et al., 1980).

Although the pathovar system was viewed as an interim expedient, and there have been many complaints about it, insufficient work has been done to replace it with an improved, more acceptable taxonomic scheme. In one study (Janse, 1982), a pathovar of *P. syringae* was elevated to the level of subspecies, *P. syringae* subsp. *savastanoi*, but this work was seriously flawed because the properties used to distinguish it from *P. syringae* do not separate it from closely related pathovars. A comprehensive comparative study is critically needed of all recognized species and pathovars.

Considerable information is available indicating that the various pathovars of *P. syringae* are for the most part distinct entities and deserve taxonomic recognition. DNA-DNA homologies within the *P. syringae* group of pathovars (Table 1) range from 37 to 100% (Denny et al., 1988a; Palleroni et al., 1972; Pecknold and Grogan, 1973). Furthermore, the range of homologies within a pathovar is similar to that within *P. aeruginosa*, a so-called “good” species. Usually, strains of a pathovar are phenotypically similar to each other and can be distinguished on the basis of nutritional utilization patterns from strains of other pathovars (Denny, 1988; Hildebrand, 1973; Hildebrand et al., 1988). Table 2 lists some properties useful for identification of certain pathovars.

A system of three-dimensional modeling of various bacterial characteristics has been

Table 1. DNA-DNA homology values for fluorescent phytopathogenic pseudomonads and related species.

After Palleroni et al. (1972) and Pecknold and Grogan (1973).

developed to help show bacterial relationships (Hildebrand et al., 1982; Hildebrand et al., 1984). DNA-DNA hybridization data most often are used to model the relationships; such a model has been made for a limited number of pathovars of *P. syringae* (Hildebrand et al., 1988). A set of coordinates was given to enable the preparation of a physical model of the three-dimensional relationships. These models are useful because phenotypic characteristics can easily be superimposed (mapped) upon them. When this is done, it is observed that strains having a given property usually lie adjacent to each other forming a cluster (Hildebrand et al., 1987). Examination of the boundaries of a phenotypic cluster often indicates why there are problems in the identification of strains; some strains appear to be “intermediate” between clusters. The mapping also indicates the range of variation that might be expected for specific taxa. Pathogenicity also can be mapped upon these models; it behaves as any other phenotypic property. The boundaries of host ranges often overlap in different ways among closely related strains. Examples of this are *P. s. pv. maculicola*, which is phenotypically closely related to *P. s. pv. tomato*. It infects tomato plants and crucifers; *P. s. pv. antirrhini*, which also is phenotypically close to *P. s. pv. tomato*, infects tomato (Hildebrand et al., 1984). It follows, therefore, that pathogenicity, the basis of the pathover system, is not a completely reliable character for the identification of a pathogen (Hildebrand et al., 1987). Rather, identification should be based upon phenotypic characterization and genetic information such

as DNA hybridization or restriction fragment-length polymorphisms (RFLPs). This should be complemented later by pathogenicity and host range tests.

The taxonomic situation in the saprophytic group of fluorescent pseudomonads, which includes many root-associated strains, is similar to that occurring in the pathogens. Stanier et al. (1966) in their nutritional study of the nonphytopathogenic pseudomonads, indicated that they took a broad view in proposing species. They placed most strains into two species, *P. fluorescens* and *P. putida*, which then were divided into several biotypes or biovars. Later, however, Micheal Doudoroff told us that he believed that these two species represented at least 500 actual species.

Reasons for the existing confusion are evident by examination of the DNA-DNA hybridization study of Palleroni et al. (1972). They showed that the homology of 15 strains of *P. putida* to the type strain ranged from 18 to 86%, a very large range to represent a species. This strain also had much greater homology to a *P. fluorescens* strain (45%) than to a number of *P. putida* strains. Likewise, the range of homology values within biovars 1, 2, and 3 of *P. fluorescens* was very large (21 to 81%). Most values were from about 50 to 65%. The relatively low genetic relationships among the strains studies thus far suggests that phenotypic variability also should be great. This is the case; many of the tests presented in *Bergey's Manual of Systematic Bacteriology* (Palleroni, 1984b) are listed as being variable for various taxa (see also Introduction to the Family Pseudomonadaceae in the second edition).

Symbols: +, product formed or substrate utilized; –, product not formed or substrate not utilized; V, variable results with different strains; W, weak positive.

^aIndicates the pH at which pitting (sinking of colonies) occurs on pectate gels; –, no action on pectate; NT, not tested. For best results, the low pH pectate gels should be at pH 4.6 or lower (Burki, 1973).

From Hildebrand and Schroth (1972), Hildebrand and Caesar (1989), Hildebrand et al. (1988), and D. C. Hildebrand (unpublished observations).

Identification of root-associated pseudomonads usually is difficult. Many strains appear to be different from those on which various taxonomic keys have been based. Their properties appear to be “intermediate” among several recognized species or biovars. In many cases, they cannot be assigned to either *P. putida* or *P. fluorescens* with certainty. As with the phytopathogens, a very large comprehensive DNA hybridization study is needed to provide background for phenotypic mapping. The completion of this should enable an understanding of the relationships among strains and the development of a more useful identification scheme.

The Nonfluorescent Group of Phytopathogenic *Pseudomonads*

The nonfluorescent phytopathogenic pseudomonads belong to two different rRNA branches (De Vos et al., 1985). Previous interpretations of rRNA-DNA homology data (Byng et al., 1983;

Kerstens and De Ley, 1984) have suggested that *Alcaligenes* species are intermingled among various pseudomonads on these branches. Three-dimensional modeling of rRNA-DNA homology data, however, suggests quite the contrary—*Alcaligenes* strains form their own cluster that are distinct from either pseudomonad branch (D. Hildebrand, unpublished observations).

The *P. acidovorans* branch consists of the recognized phytopathogenic species *P. asplenii*, *P. avenae*, *P. pseudoalcaligenes* subsp. *citrulli*, and *P. rubrilineans*, and as noted earlier, probably *P. pseudoalcaligenes* subsp. *konjaci*. The members of this group have not been studied well and their overall relationship to each other and other members of the *P. acidovorans* (now *Comamonas acidovorans*) group are unknown.

P. solanacearum and related species comprise the second nonfluorescent rRNA branch. The recognized phytopathogenic species in this group include *P. andropogonis*, *P. caryophyllii*, *P. cepacia*, *P. gladioli*, *P. glumae*, *P. rubrisubalbi-*

cans, and *P. woodsii*. Unlike the fluorescent group, the species concept in this group of phytopathogenic pseudomonads always has been broad. *P. solanacearum* in particular has been extensively studied since its description by Smith (1896). Many of these studies—including DNA-DNA homology (range: 54–100%), physiological tests, and pathogenicity tests—indicated that this species consisted of a heterogeneous group of organisms. Just as there is little agreement about the subdivision into species of the *P. syringae* group of fluorescent pseudomonads, there is little agreement about the subdivision of *P. solanacearum* into groups. Okabe and Goto (1963) reported that *P. solanacearum* strains could be divided into 40 or more groups by biochemical and serological properties, and phage and bacteriocin reactions. These groups did not correlate in general with the 13 pathovars they designated (Okabe and Goto, 1961). Hayward (1964) indicated that *P. solanacearum* strains fell into four biovars on the basis of phenotypic characteristics, whereas Baptist et al. (1971) discerned only two by enzyme electrophoresis studies. Most workers generally use either the three races scheme described by Buddenhagen and Kelman (1964) or the four biovars system described by Hayward (1964). It is recognized, however, that these races (Buddenhagen and Kelman, 1964) or biovars (Harris, 1972; Hayward, 1964; Keshwal and Joshi, 1976) are not uniform, but consist of numerous and unknown pathovars or subtypes.

Recent work with RFLPs (Cook and Sequeira, 1988; Cook et al., 1989) suggests that some of these groups could be redefined. Their conclusions were that *P. solanacearum* could be divided into two distinct groups. Group 1 included strains of race 1 biovars 3 and 4; group 2 included strains of race 1 biovar 1 and races 2 and 3. Furthermore, they could not distinguish strains of the pathogen by both race and biovar simultaneously. Race 1 was highly variable strains of race 2 (from banana) fell into 3 distinct groups, and race 3 strains were homogeneous. Whereas these results are encouraging, a word of caution must be made about taxonomic conclusions drawn through use of RFLPs. RFLPs may be helpful for the identification of various groups of strains. However, the relationships of groups to each other is much more difficult to ascertain using RFLPs. We have found (unpublished observations) that relationships derived from RFLP data often do not correlate with relationships obtained from DNA hybridization data. For example, RFLP data suggest that *X. campestris* pv. *phaseoli* “var. *fuscans*” is quite distinct from *X. campestris* pv. *phaseoli* (Gabriel et al., 1989). Our DNA hybridization work confirms this relationship. On the other hand, the RFLP

data indicated that *X. c.* pv. *phaseoli* was as distantly related to *X. c.* pv. *glycines* as to *X. c.* pv. *campestris*. DNA hybridization indicates that *X. c.* pv. *phaseoli* is closely related to *X. c.* pv. *glycines* but distantly related to *X. c.* pv. *campestris*.

P. cepacia represents another large and presumably diverse group of phytopathogens; the DNA-DNA homology ranges from 46 to 79% (Ballard et al., 1970). It was originally described as a pathogen causing soft-rot disease of onions, but later was broadened to include strains isolated from soil, water, and clinical specimens previously known as *P. multivorans* and *P. kingii* (Ballard et al., 1970; Snell et al., 1972; Sinsabaugh and Howard, 1975). *P. cepacia* is the most nutritionally versatile of all of the pseudomonads, pathogenic or saprophytic (Ballard et al., 1970); fourteen of the 18 strains tested utilized at least 102 of the 136 substrates screened.

P. gladioli appears to be a somewhat more tightly clustered species than either *P. solanacearum* or *P. cepacia*. Originally described as causing a rot of gladiolus, its description was broadened by Ballard et al. (1970) to include *P. allicola*, another onion pathogen. DNA-DNA homologies (79–82%) suggested a close relationship between these bacteria but, if the situation in the *P. syringae* group of pathogens is any indication, these organisms probably have distinctive pathogenic properties and should be taxonomically separated. Several phenotypic differences also were observed, such as the propensity of *P. allicola* to produce a darkening of culture media upon aging and a negative or very weak oxidase reaction.

P. caryophylli, the carnation pathogen, is another noteworthy plant-pathogenic species. It may be a very homogeneous species since DNA-DNA homologies of three strains ranged from 99 to 100% (Ballard et al., 1970). This species is nutritionally less versatile than either *P. cepacia* or *P. gladioli*, and it is more host- or habitat-restricted.

P. andropogonis is an interesting organism. It is placed as an intermediate between the *P. solanacearum* and *P. acidovorans* rRNA branches on the basis of three-dimensional modeling of rRNA-DNA hybridization data. Although it appears more closely related to *P. solanacearum* on the basis of rRNA similarity (De Vos et al., 1985), it belongs in an enzymological patterning group found otherwise only in the *P. acidovorans* rRNA branch (Byng et al., 1983).

Genetics and Mechanisms of Pathogenesis

Major developments in the genetics of phytopathogenic pseudomonads occurred during the

Table 3. Some genetic studies in phytopathogenic pseudomonads.^a

^aThe table is not meant to be inclusive of all group members or relevant genes. Tn: transposon; IS: insertion sequence; MEX: marker exchange; RFLP: restriction fragment length polymorphism. Gene designations: *avr*: avirulence; *hsp*: host specificity; *hrp/hri*: hypersensitive reaction and pathogenicity; *path*: pathogenicity; *lem*: lesion formation; *egl*: endogalacturonate lyase; *pgl*: polygalacturonate lyase; *recA*: homologous recombination; *argF*: ornithine carbamoyltransferase; Cu^r: copper resistance; *flu/sid*: fluorescence/siderophore genes; *ice*: ice nucleation gene; *iaa*: indoleacetic acid production; *tzs*: transzeatin synthesis; (*): function established in a related pathovar.

^bSymbols: A: *P. solanacearum*; B: *P. viridiflava*; C: *P. cepacia*; D: *P. syringae* (nonpathogenic); E–O: *P. syringae* pathovars; E: *savastanoi*; F: *syringae*; G: *phaseolicola*; H: *glycinea*; I: *tabaci*; J: *tomato*; K: *maculicola*; L: *morsprunorum*; M: *atropurpurea*; N: *mori*; O: *pisi*.

1980s following an exploratory phase during the 1970s. Although the full impact of these developments on physiological, biochemical and other areas has not yet been realized, we seem to be close to making major advances in our understanding of pathogenic mechanisms of these bacteria (Kerr, 1987). Table 3 shows the range of activity and focus in several “model” members. Only some areas, in which more definitive studies have been carried out, are discussed. Several excellent reviews are cited which cover these and many other relevant subjects.

Genetic Linkage Analysis

Conventional methods for chromosome mapping have been applied to four pathovars of *P. syringae*. The most extensive linkage analysis available is in *P. s. syringae* (see Holloway and Morgan, 1986). The order and spacing of isofunctional loci on this chromosome resemble overall that in the more extensively mapped chromosomes of *P. aeruginosa* and *P. putida*. The relative order of nine auxotrophic loci and an antibiotic

resistance gene has been determined in the *P. s. pv. glycinea* by three factor crosses (Leary and Fullbright, 1982). Several pairs of loci showed transductional linkage in *P. s. pv. morsprunorum* (Errington and Vivian, 1981). Co-transfer of genetic markers was also reported in *P. solanacearum* (Boucher and Sequeira, 1978).

There are no long-range linkage data on genes related to pathogenicity, toxin, or phytohormone production except for those located on plasmids. In *P. solanacearum*, a locus related to methionine biosynthesis (*met*) appears to be linked to a group of pathogenicity genes (*hrp*), a host specificity gene and genes determining acridine orange resistance, lipo- and exopolysaccharide production and composition, and production of a brown pigment in rich medium (Boucher et al., 1987, 1988a, 1988b). Some short-range linkage information has been provided by cloning experiments. For example, several groups or clusters of functionally related genes have been cloned in single cosmids and genomic Tn5 insertion mutants altered in pathogenicity or toxin production. These have been localized in single large

restriction endonuclease fragments. Examples are the *hrp* clusters of *P. syringae* pathovars *phaseolicola*, *glycinea*, and *syringae*, and *P. solanacearum* (in the last two the region may include host specificity genes); genes for phaseolotoxin synthesis along with a gene for the phaseolotoxin-insensitive ornithine carbamoyl-transferase in *P. s. pv. phaseolicola*; genes involved in tabtoxin, syringomycin/syringotoxin production in pathovars *tabaci* and *syringae*, respectively; and the plasmid-borne genes for indole acetic acid (IAA) synthesis and copper resistance in pathovars *savastanoi* and *tomato*, respectively (Barta et al., 1988; Comai and Kosuge, 1980; Comai et al., 1982; Cooksey 1987; Glass and Kosuge, 1986; Huang et al., 1988; Joe et al., 1988; Lindgren et al., 1986; Mellano and Cooksey, 1988; Morgan and Chatterjee, 1985, 1988; Peet et al., 1986; Peet and Panopoulos, 1988; Xu and Gross, 1988a, 1988b; T. V. Huynh, D. Dahlbeck, and B. J. Staskawicz, unpublished observations).

The chromosomes of the well-studied *Pseudomonas* species contain "supraoperonic clusters" that include functionally related genes. reference is not an exact match Wheels (1975), and Holloway and Morgan (1986) discussed the possible evolutionary significance of this features and underlying mechanisms that may have shaped the evolution of *Pseudomonas* chromosomes. It would be interesting to know if the various clusters of genes involved in pathogenicity, toxin production, or other aspects of *Pseudomonas*-plant interactions are located on a separate chromosomal arc like the catabolic genes in the nonphytopathogenic members.

Gene Transfer, Cloning, and Transposon Delivery Systems

Several conjugative plasmids have been described in the phytopathogenic *Pseudomonas* (Coplin, 1982; Panopoulos and Peet, 1985; Shaw, 1987). However, these have not been exploited to a great extent in genetic studies. Researchers have instead used other such elements developed for similar work with *Rhizobium*, *P. aeruginosa*, and other nonenteric prokaryotes. These elements are related to or derived from the broad host-range plasmids of the IncP, IncW, and IncQ groups. A wide variety of modifications (size reduction, addition/inactivation/deletion or substitution of selectable markers or mobilization/replication origins, addition of the *cos* fragment from coliphage lambda, incorporation of strong or regulatable promoters, synthetic multi-linkers, transcriptional terminators, easily scorable or assayable markers, and promoterless reporter genes) has produced an extensive array of versatile tools for cloning, transposon mutagenesis, analysis of promoter function, and

other similar investigations (Denhardt and Colasanti 1988; Franklin 1985). Some applications of these tools have been reviewed in Mills (1985), and Chatterjee and Vidaver (1986).

Plasmids

The presence of one or more plasmids in this group of bacteria is the rule rather than the exception (Coplin, 1982; Panopoulos and Peet, 1985; Shaw, 1987) but the plasmid complement is rarely identical among strains of the same infra-subspecific group (Shaw, 1987). Several associations between plasmids and phytopathologically significant traits have been reported. Examples are the megaplasmids of *P. solanacearum* (Boucher et al., 1986, 1988a, 1988b) and the IAA/cytokinin plasmids of *P. s. pv. savastanoi*, which are discussed elsewhere in this chapter, and plasmids involved in production of the phytotoxin coronatine in several pathovars (Bender et al., 1987; Sato et al., 1983; Willis and Leary, 1984). A plasmid of *P. s. pv. phaseolicola* reversibly integrates into the chromosome (Curiale and Mills, 1982) and a chromosome-mobilizing agent occurs in *P. s. pv. mors-prunorum* (Errington and Vivian, 1981). The copper resistance plasmid of *P. s. pv. tomato* (Cooksey, 1987) and the transmissible streptomycin resistance elements in *P. s. pv. lachrymans* (Yano et al., 1983) and *P. s. pv. papulans* (Burr et al., 1988) are three other examples with agro-nomic significance.

Phenotypes of Mutants Altered in Plant Responses

There is general consensus that when a search is undertaken for the isolation of mutants affected in pathogenicity, virulence, or other similar properties, auxotrophic requirements must not be involved because they may prevent pathogen multiplication in the plant even if other mutations are not present. This precaution has been applied in all relevant cases discussed in this chapter.

The search for mutants that remain prototrophic but are altered in pathogenicity on host cultivars or in the reactions they elicit on non-host species has produced four basic mutant types: 1) the "null" type (e.g., *Hrp*⁻, *Mri*⁻ that are unable to elicit hypersensitive responses (HR) on either non-host plants (Klement, 1963) or on susceptible cultivars of the host species 2) those unable to cause disease symptoms on either leaves or other susceptible organs such as pods (e.g. *Lem*⁻, *Path*⁻) but still able to elicit the HR reaction; 3) those no longer eliciting HR on a resistant host cultivar(s) but produce instead typ-

ical disease symptoms ("compatible" reaction); 4) mutants with reduced host range, having lost the ability to cause disease on some host species cultivars but retaining full virulence toward others and eliciting HR on the formerly susceptible cultivars and on non-host species. Attenuated mutants that show varying degrees of residual pathogenicity (e.g., smaller or fewer lesions, or require higher inoculum concentration to produce symptoms) with either normal or reduced ability to elicit HR on one or more non-host plants at given inoculum concentrations have also been obtained. It is not certain that these mutants represent a genetically distinct class since partial inactivation of genes or generation of promoters by Tn5, the most commonly used transposon, could in theory lead to partial loss of target gene function (Deasey and Matthysse, 1988; Harper et al., 1987; Joe et al., 1988; Lindgren et al., 1986; Malik et al., 1987; Niepold et al., 1985; Salch and Shaw, 1988; Somlyai et al., 1986; Willis et al., 1990). Some of the mutant types above also have been isolated in other phytopathogenic bacteria (Daniels et al., 1988). However, no mutants that are pathogenic but unable to elicit HR on a non-host have been found. Types 1 and 3 above exemplify two distinct categories of genes that are further discussed below.

The *hrp* Clusters of *P. syringae* Pathovars and *P. solanacearum*

Studies by Lindgren et al. (1986) showed that a contiguous region (about 20 kb) and an additional unlinked locus in the *P. s. pv. phaseolicola* genome encoded functions that were necessary for the expression of two phenotypes thought to be mutually exclusive, namely the production of primary disease symptoms (watersoaked lesions) on bean, the susceptible host, and the elicitation of the hypersensitive reaction on tobacco and on three additional non-host species (tomato, soybean, and cowpea) that were examined. The acronym *hrp* (phonetic "harp," for hypersensitive reaction and pathogenicity) was used to designate these genes. Although other designations have been used for phenotypically similar mutants (e.g. Hri, Path/HR), the *hrp* acronym has been adopted for such mutants in other pathovars of *P. syringae* (Huang et al., 1988; T. V. Huynh, D. Dahlbeck, and B. J. Staskawicz, unpublished observations) and in *P. solanacearum* (Boucher et al., 1987, 1988a, 1988b) which have *hrp* clusters of similar size. DNA hybridization, marker exchange mutagenesis, or interpathovar complementation showed that the *hrp* genes are present in many pathovars of *P. syringae*. Functional equivalence has been demonstrated for two *hrp* clusters of *P. s. pv. phaseoli-*

cola with their corresponding homologues in pathovars *glycinea*, *tabaci*, *angulata* and *savastanoi* (Lindgren et al., 1988; Grimm and Panopoulos, unpublished observations), which share a high degree of total DNA homology with each other. Phenotypically similar mutants have also been obtained in *Erwinia amylovora* (Steinberger and Beer, 1988) and in pathovars of *Xanthomonas campestris* (Staskawicz, personal communication) both of which are phylogenetically distant from *Pseudomonas*. Hybridization analysis with *hrp* probes suggests at least two *hrp* homology groups exist among different phytopathogenic taxa. Homology to the *P. s. pv. phaseolicola* probes appears to be restricted to pathovars of *P. syringae* while the probes from *P. solanacearum* also hybridized to DNA from *Xanthomonas* (Boucher et al., 1987; Lindgren et al., 1988).

Proteins that are present in the wild type strains but are absent from *Hrp*⁻ (*Hri*⁻) mutants also have been detected in gels by immunological techniques using whole cell antisera, maxicell analysis of *hrpM* and a coupled transcription/translation system for *hrpS* (Xu et al., 1988; C. Grimm and N. J. Panopoulos, unpublished observations; Mukhopadhyay et al., 1988; Niepold and Huber, 1988; Somlyai et al., 1986). However, there are few clues about the biochemical functions of these proteins and *hrp* genes in general in disease and hypersensitive necrosis development. Baker et al. (1987) reported that the K⁺/H⁺ exchange reaction observed in cells undergoing HR was associated with *hrp* gene function. The same group also reported that a cosmid clone carrying the *hrp* cluster of a *P. s. pv. syringae* strain imparted HR-like necrosis-inducing ability (but not pathogenicity) in *P. fluorescens* and in *E. coli*. Further genetic analysis in this system may provide important functional information by taking advantage of the wealth of genetic knowledge available in *E. coli*.

Primary sequence data for a *hrp* locus (*hrpS*) of *P. s. pv. phaseolicola* suggested that its protein product is regulatory, as it shared significant homology (41 to 48% identical residues) to a highly conserved domain of several prokaryotic regulatory proteins. These included the nitrogen assimilation regulator protein NtrC, the *nif* gene activator protein NifA, the C-4-dicarboxylate transport regulator protein DctD, and the tyrosine repressor TyrR (Grimm et al., 1989; C. Grimm and N. J. Panopoulos, 1989). The *hrpS* gene was subsequently shown to be necessary for the activation of several other *hrp* genes in *P. s. pv. phaseolicola* that are induced during early stages of pathogenesis and hypersensitive necrosis and also in response to nutritional downshift (C. Grimm and N. J. Panopoulos, unpublished observations; M. N. Mindrinos, L. G. Rahme, and

N. J. Panopoulos, unpublished observations; Rahme et al., 1990). Nucleotide sequencing also predicted that a protein homologous to HrpS is encoded by an adjacent gene, *hrpR*, both in *P. s. pv. phaseolicola* and in *P. s. pv. glycinea* (C. Grimm, N. J. Panopoulos, B. J. Staskawicz, and D. Dahlbeck, unpublished observations). This protein presumably plays a regulatory role but its promoter specificity is not yet known. It further appears that the *hrpS-hrpR* region and an additional locus (*hrpL*) are necessary for the expression of an avirulence gene (*avrB*) of *P. s. pv. glycinea* in response to a nutritional downshift and also in planta (T. V. Huynh, D. Dahlbeck, and B. J. Staskawicz, unpublished observations).

Complete nucleotide sequences for *hrpS* have been determined for three pathovars, *phaseolicola*, *glycinea*, and *savastanoi*. It also has been determined for the *hrpR* gene in the first two and for the unlinked locus, *hrpM*, in pathovars *phaseolicola* and *syringae* (R. Frederick and N. J. Panopoulos, unpublished observations; Mukhopadhyay et al., 1988). The latter locus is structurally unusual in that it contains four large, antiparallel open reading frames in codon-to-codon register over most of their length. Only two of these were shown to be functionally important. One of them encodes an 83 kDa protein with several membrane-spanning segments, and the other encodes a 42 kDa protein which shares homologous stretches with histones. The *hrpM* is the only *hrp* locus known to control bacterial colony phenotype (mucoidy).

The *hrp* cluster of *P. solanacearum* is similar in size to that of other pseudomonads and shows many similar features and some other interesting properties (Boucher et al., 1988a, 1988b). The region is conserved in all 52 strains of the pathogen representing all different races, biovars, and geographical origins. In most strains, possibly all, the cluster is located on a megaplasmid and is deleted entirely in Acr;xr (acridine orange resistant) mutants. These mutants also exhibit methionine auxotrophy, secrete a brown pigment during growth in rich medium, and differ from the wild type in the structure of their lipo- and exopolysaccharides (Drigues et al., 1985). Chemically defined changes in LPS structure have previously been described for a well known class of spontaneous avirulent mutants ("B-one" type) and for mutants selected for resistance to an LPS-specific phage (Hendrick and Sequeira, 1984). The B-one mutants are altered in several other properties (production of fimbriae, attachment to host cells, aerotaxis, motility, and production/secretion of cell wall degrading enzymes). Genes for pilus synthesis and extracellular enzyme production (*egl*) were recently cloned but their relationship to gene carried by

the *hrp* cluster is not yet clarified (Denny et al., 1988b; Roberts et al., 1988; Schell, 1987; Stemmer and Sequeira, 1987). An interesting new development is the identification of a gene encoding a genotype-specific HR-like necrosis eliciting protein from a strain that is pathogenic on potato (Xu et al., 1988). These findings coupled with the functional characterization of the *hrp* cluster should help clarify the seemingly complex genetics and physiology of vascular wilt pathogenesis by *P. solanacearum*.

Avirulence Genes

The term "avirulence gene" was coined to describe those genes in a pathogen that relate to a product recognized by the host and causing an incompatible reaction, hence no disease. Flor's gene-for-gene hypothesis (Flor, 1971) provided a framework for understanding the genetics of specificity in plant-pathogen interactions. A commonly held interpretation of this hypothesis predicts that specificity between host and pathogen resides in the incompatible interaction which is genetically determined by dominant genes in the host and the pathogen. These genes are generally termed "resistance" and "avirulence" genes, respectively. The cloning of "avirulence" genes from *P. s. glycinea* (Staskawicz et al., 1984) provided an elegant verification of this hypothesis at the molecular level and its applicability to a bacterial pathogen. This study and those which followed (Napoli and Staskawicz, 1987; Tamaki et al., 1988; Keen and Staskawicz, 1988) demonstrated that race-cultivar specific incompatibility, expressed as hypersensitive response in the soybean blight-*P. s. pv. glycinea* system requires the functions of distinct genes (*avr*) for different resistance genes in the host cultivar. Mutational inactivation of a given *avr* gene changes the incompatible interaction (HR) to a compatible one (development of watersoaked lesions) on cultivars that are known or can be presumed to possess a functionally complementary gene for resistance, while the interaction with cultivars lacking such a gene remains the same. Similar changes in reaction type on such cultivars may be obtained when the functionally correspondent *avr* gene in the pathogen is inactivated. Interstrain transfer of a given *avr* gene changes the interaction phenotype in the opposite direction. Thus, both types of analysis produce the result predicted from the gene-for-gene hypothesis.

Avirulence genes have been cloned from several other pathovars of *P. syringae*, including *tomato* (Kobayashi et al., 1989) and *phaseolicola* (Harper et al., 1988; Shintaku et al., 1989), and from several pathovars of *Xanthomonas* (Gabriel et al., 1986; Swanson et al., 1988; Kearney

et al., 1988; Keen and Staskawicz, 1988). Four of them have been sequenced and their products identified (Napoli and Staskawicz, 1987; Ronald and Staskawicz, 1988; Tamaki et al., 1988). However, the functions of Avr proteins are still unclear. Necrosis-inducing activity has been associated with the *avrD* gene, which was cloned from *P. s. pv. tomato* (Kobayashi et al., 1989), when it is expressed from a strong promoter in *E. coli* (N. T. Keen, personal communication). This has not yet been demonstrated for other *avr* genes. Also unclear is the relationship, if any, between the *avrD* necrosis elicitor, the 60 kDa genotype-specific necrosis elicitor of potato described in *P. solanacearum* (Xu et al., 1988) and the K⁺/H⁺ exchange promoting substance(s) produced by *P. fluorescens* harboring the *P. s. syringae* *hrp* cluster (Baker et al., 1987). Detailed characterization of the active molecular species in these cases should be forthcoming.

As discussed earlier in this chapter, the phenotypic expression of HR by *Pseudomonas* requires *hrp* gene function in addition to *avr*. The existence of Hrp- mutants, particularly in pathovars from which *avr* genes were cloned, reveals a genetic dependence of *avr*-mediated incompatibility on *hrp* gene function. This dependence is specifically shown by the fact that the hypersensitive necrosis elicited by *P. s. pv. glycinea* race O on cultivars Acme and Harosoy, where the only functionally relevant *avr* genes are *avrC* and *avrB*, respectively, is no longer elicited when the *hrp* region is not functional (Lindgren et al., 1988). This suggests that *avr* and *hrp* genes or their products interact with each other, either directly or indirectly, and that these interactions are an important part of the chain of events leading to the elicitation of HR and incompatibility. The nature of these interactions is largely unexplained except for one *avr* gene (*avrB*) whose transcription requires the function of certain *hrp* genes in *P. s. pv. glycinea* (T. V. Huynh, D. Dahlbeck, B. J. Staskawicz, unpublished observations). Whether similar regulatory requirements exist for other avirulence genes is not known. However, other types of *avr-hrp* gene interactions must also occur. For example, expression of *avrB* does not require the functions of the majority of *hrp* genes, which are nevertheless necessary for necrosis development (Huynh et al., 1989).

Avirulence genes were recently shown to impart new pathogenic specificities of *Pseudomonas* on non-hosts (species and genus level). (Kobayashi et al., 1989; Whalen et al., 1988) For example, specific cosmid clones from *P. s. pv. tomato* changed the compatible interaction of *P. s. pv. glycinea* to incompatible on certain soybean cultivars but not on others (Kobayashi et al., 1989). *P. s. pv. tomato* was later

shown to contain an homologue of the *P. s. pv. glycinea* *avrA* gene which could impart avirulence on *P. s. pv. tabaci* but not on pathovars *pisi*, *phaseolicola* and *lachrymans*. Similar results were obtained through transfer of genomic libraries or specific avirulence genes between *Pseudomonas* and *Xanthomonas* (Whalen et al., 1988). These findings have a very interesting implication, namely, that *avr* genes (i.e. genetically dominant negative factors) are a common class of host range determinants in non-host/pathogen interactions.

Toxins

Several pathovars of *P. syringae* produce phyto-toxins (Durbin, 1981; Mitchell and Bielecki, 1977; Mitchell, 1984). Chemical structures have been established for four of these toxins as well as rhizobitoxin which was recently reported as being produced by *Pseudomonas andropogonis* (Daly and Deverall, 1983; Durbin, 1981; Mitchell, 1984, 1988; Moore et al., 1984). Known sites of action include amino acid biosynthetic pathway enzymes (e.g. glutamine synthetase and ornithine carbamoyltransferase for the active moieties of tabtoxin and phaseolotoxin, respectively), chloroplast RNA polymerase for tagetitoxin, cystathionase for rhizobitoxin, and certain protein kinases of plant and other eukaryotic cells for syringomycin (Abdel-Ghany et al., 1988; Bidwai and Takemoto, 1987; Gilchrist, 1983; Langston-Unkefer et al., 1987; Mitchell, 1984; Tam and Patil, 1972; Templeton et al., 1985). Several of these toxins are capable, in purified form, of reproducing one or more aspects of disease symptomatology attributed to them, usually chlorosis or necrosis. The causal relationships between the effect of the toxin on the target site and expression of disease symptoms are less clear (Gilchrist, 1983; Mathews and Durbin, 1987; Mitchell, 1984; Turner and Mitchell, 1985; Turner and Taha, 1984).

In contrast to the phytotoxins produced by fungal pathogens, which are host-specific, the *Pseudomonas* toxins are active against plants on which their producers do not cause disease. Some of these toxins are also active against microorganisms. The latter property has been exploited by researchers to develop convenient bioassays that have expedited purification and mode of action and genetic studies on these toxins (Gasson, 1980; Gross et al., 1977; Mitchell et al., 1980; Morgan and Chatterjee, 1985; Peet and Panopoulos, 1986; Staskawicz and Panopoulos 1979; Turner and Taha, 1984; Xu and Gross, 1988a). Genetic studies have been reported for five *Pseudomonas* toxins. Genes involved in toxin production have only been detected by hybridization in organisms already known to

produce these substances, suggesting possible uses as diagnostic probes. For example, a *tox* gene fragment from *P. phaseolicola* has proven useful as a diagnostic probe (Schaad et al., 1989) and similar possibilities exist for other pathogens.

Whether toxins constitute "pathogenicity" or "virulence" factors (*sensu* Yoder 1980) has been actively debated among plant pathologists. As with other pathogenicity or virulence genes, the operational criteria for making such distinctions are not uniformly applied by investigators, and disease symptomatology, usually studied only in the laboratory, differ enough from one case to another to confuse the picture. Nevertheless, some *Pseudomonas* toxins clearly belong to the second group, one example being phaseolotoxin. Mutants of *P. s. pv. phaseolicola* that do not produce phaseolotoxin show identical growth kinetics in the plant as do wild-type strains (Patil et al., 1974; Peet et al., 1986). Other *Pseudomonas* toxins that have been examined in this respect (e.g. coronatine, syringotoxin) appear to play a role in pathogen multiplication in the plant since *Tox-* mutants of *P. s. pv. tomato* and *P. s. pv. syringae* (citrus strain) were attenuated in virulence (Bender et al., 1987; Xu and Gross, 1988a).

Two *Pseudomonas* toxins, syringomycin and syringotoxin, are cyclic peptides containing one or more nonprotein amino acids and are presumed to be synthesized by enzyme systems analogous to those involved in the synthesis of cyclic peptide antibiotics. Large-molecular-weight proteins or protein complexes have been identified that are thought to be toxin synthetases (Morgan and Chatterjee, 1988; Xu and Gross, 1988b). Two other toxins, tabtoxin and phaseolotoxin, are synthesized and secreted from the cells as linear peptides but are hydrolyzed in the plant to a nonpeptide form (tabtoxinine- β -lactam and N-[phosphosulphinyl] δ alanine, abbreviated Psorn, respectively) which is considerably more active against the target enzyme. Cleavage by plant peptidases potentiates the action of these toxins *in vivo*. This strategy may be a means of exploiting general oligopeptide permeases for the "illicit" transport at least into microbial cells (Staskawicz and Panopoulos, 1979), and may also be part of the strategy for self-protection in the producer strains (Durbin and Langston-Unkefer, 1988). However, both *P. s. pv. tabaci* and *P. s. pv. phaseolicola* have additional self-protection mechanisms: the first through biochemical modification of its glutamine synthetase to a form not sensitive to the toxin and perhaps also through formation of a tabtoxin-hydrolyzing periplasmic aminopeptidase, and the second through a duplicate ornithine carbamoyltransferase that is much less

sensitive to phaseolotoxin and Psorn and is produced only during periods of toxin synthesis (Durbin and Langston-Unkefer, 1988; Ferguson et al., 1980; Knight et al., 1986, 1987; Levi and Durbin, 1986; Peet and Panopoulos, 1988; Staskawicz et al., 1980).

Phytohormones

Phytohormones represent the only group of low-molecular-weight bioactive substances besides the toxins for which a role in pathogenesis by *Pseudomonas* is rigorously established. A useful conceptual distinction between toxins and phytohormones is that the latter are also produced by the host. A role for phytohormones is usually suspected when pathogens induce growth abnormalities in the host, examples being the crown gall, hairy root, and olive knot diseases. However, surveys (Akiyoshi et al., 1987; Fett et al., 1987) based on cytokinin radioimmunoassay and a combination of analytical techniques for detection of indoles demonstrated for IAA and related indoles showed that other pathogens that do not cause hypertrophic symptoms on their hosts also produce these substances. Thus, nine different plant pathogenic pseudomonads produce IAA and additional indole compounds in media that have been supplemented with tryptophan. *P. solanacearum* and *P. s. pv. syringae* also synthesize exceptionally high amounts of IAA both in the presence and absence of exogenous tryptophan (Fett et al., 1987; Phelps and Sequeira, 1967). A role of hormones in either vascular wilt or in the brown spot disease has not been established. IAA has numerous other effects on plant cells which may favor bacterial multiplication in the absence of hypertrophy.

There is definitive evidence for the involvement of IAA in the interaction between *P. s. pv. savastanoi* and two of its hosts (Morris, 1986; Nester and Kosuge, 1981; Schroder, 1987). The pathogen synthesizes the hormone from tryptophan in two steps catalyzed by tryptophan monooxygenase and indoleacetamide hydrolase, the products of the *iaaM* and *iaaH* genes, respectively. The functions of *iaaM* and *iaaH* are essential for the hyperplastic response. Strains of *P. s. pv. savastanoi* that incite hyperplasias on oleander and olive differ genetically from strains that are only pathogenic on olive in two respects: first, they carry the *iaaM* and *iaaH* genes on plasmids (pIAA) rather than on the chromosome; second, they possess an additional gene, *iaaL*, that encodes an IAA-lysine conjugating enzyme, which apparently regulates the IAA-pool size in oleander strains. The *iaaL* gene also is carried on pIAA plasmids and behaves as a positive host range determinant of gall-forming ability on ole-

ander. When it is inactivated, only minor swellings are formed on this host (Glass and Kosuge, 1988) rather than typical galls. Unlike the crown gall disease, there is no evidence for *iaa* gene transfer to plant cells by *P. s. pv. savastanoi*.

Several groups (Akiyoshi et al., 1987; Morris, 1986; Surico et al., 1985) have reported that *P. s. pv. savastanoi* and *P. solanacearum* produce cytokinins. There is diversity in both the type of cytokinins and the amounts produced by different strains. Except for *trans*-zeatin riboside, which acts as a virulence factor in *P. s. pv. savastanoi* (Roberto et al., 1988), the role of these substances in symptom expression and the basis of the diversity of the cytokinin spectra have not yet been established. In *P. s. pv. savastanoi* 1006 (an olive strain), a plasmid-borne gene (*ptz*) encodes isopentenyl transferase activity when cloned in *E. coli*. A gene designated *tzs* was also cloned from *P. solanacearum* K60, but its location and linkage were not determined (Akiyoshi et al., 1987).

The deduced amino acid sequences of *P. s. pv. savastanoi iaaM*, *iaaH* and *ptz* gene products share significant similarity to the Ti plasmid genes for phytohormone biosynthesis (*tms-1* and *tms-2* for IAA and *tzs* and *ipt* gene for cytokinin). Interesting speculations have been put forward both about the possible origins and about the evolutionary relationships of these genes. For example, Comai and Kosuge (1983) suggested that the *iaa* genes of *P. savastanoi* originated from genes for utilization of exogenous tryptophan under saprophytic conditions where IAA served as an intermediate. A simple loss of auxin degradation would lead to accumulation of the hormone. Schell (1986) and Yamada et al. (1985, 1986) further speculated that the genes for hormone biosynthesis found on Ti plasmids may have originated from those of *P. s. pv. savastanoi*. The acquisition of eukaryotic expression signals may be viewed as a highly refined improvement. This would enable a vastly expanded host range and transfer of the biosynthetic cost of hormone production from the bacterial cell to the plant (Morris and Powell, 1987; Weller and Schroder, 1987). The gene acquisition proposal further suggests that the phytohormone biosynthetic capacity of *P. s. pv. savastanoi* evolved before *A. tumefaciens* acquired the ability to form hormone-autotrophic tumors. The degree of sequence similarity between the phytohormone genes and their products (about 50%) would predict that the proposed gene transfer event occurred very early in prokaryote evolution (Ochman and Wilson, 1987). Recently, Sekine et al. (1989) suggested a common origin for *iaaH*, *tms-2*, and a gene (*bam*) encoding IAA hydrolase that was cloned from *Bradyrhizobium japonicum*. Since we know little about the origin

and evolution of plant pathogens, these hypotheses are intriguing and invite more extensive and detailed phylogenetic and molecular evolutionary consideration.

Ice Nucleation Genes and Proteins

Ice nucleating *Pseudomonas* (*Ina*⁺) are among the most efficient ice nucleators at temperatures above -10°C (Lindow, 1978; Lindow, 1983). Three species of this taxon contain ice nucleating members: *P. syringae* (various pathovars), *P. fluorescens* (biotype G), and *P. viridiflava* (several strains). The study of bacterial ice nucleation received particular attention in recent years because: 1) the role of ice nucleating bacteria, particularly *P. syringae* as agents of frost injury to plants had been well established in the 1970's; 2) a broad range of potential applications of ice nucleators in various industries exists; 3) the phylloplane, which these bacteria normally occupy, is a relatively simple environment and, therefore, more easily amenable to modification than other environments (e.g., the rhizosphere); 4) the phenomenon itself has inherent scientific interest; and 5) an important development, namely the cloning of ice-nucleation genes, occurred in 1982 (Orser et al., 1983). This made possible the analysis of the molecular, genetic and biochemical basis of bacterial ice nucleation by new high-resolution methods.

It is now firmly established that a family of large and unusual proteins (ice nucleation proteins, 118 kDa or larger) are a key component of bacterial ice nuclei (Corotto et al., 1986; Green and Warren, 1985; Lindow et al., 1989; Warren, 1987; Wolber et al., 1986; Warren, 1987). Predicted amino acid sequences of two such proteins (*InaZ* and *InaW*, from *P. syringae* and *P. fluorescens*, respectively) revealed a very interesting structure from the standpoint of ice nucleation function. Both proteins consist for the most part of about 120 tandem repeats of a "consensus" octapeptide with alternative periodicities (e.g., 16 or 48 amino acids) superimposed on this basic pattern (AGYGSTXTAGXXSSLI AGYGSTQTAGXXSXLT AGY-GSTQTAQXXSXST, the letters specifying amino acids according to the standard single-letter code, X being a variable residue). Although not unique among proteins, the repeat structure suggests itself as being central to the ice nucleation function. Several repeat domains may collectively form a catalytic surface of some critical size which effectively orders water molecules in an ice-like lattice. Although crystallographic data are not yet available, tertiary structures of ice nucleation proteins have been proposed (Warren et al., 1986; Warren, 1987).

The sequence similarity between the *inaZ* and *inaW* genes leaves little doubt that they have a common origin. It has been suggested that these genes may have evolved by amplification of an eight-codon motif (Green and Warren, 1985; Warren, 1987). It is interesting to know whether this applies to other similar genes. Nucleotide sequence data for the ice nucleation genes from *Erwinia herbicola* and *Xanthomonas translucens*, which are phylogenetically distant from the pseudomonads, may be informative as to whether the scattered distribution of ice nucleation genes among the *Pseudomonas* and other eubacterial evolutionary lines reflects common ancestry or is a result of lateral transfer.

The nature, composition, and other properties of bacterial ice nucleation sites have been analyzed at considerable depth by a variety of methods. *Pseudomonas* ice nuclei are cell-bound and contain both protein and lipid since treatment of partially purified outer membranes of *P. syringae* with either proteinase K or various delipidating agents leads to significant loss of ice nucleation activity, which can be subsequently reconstituted by addition of phospholipid (Govindarajan and Lindow, 1988a). There is one unconfirmed report (Kozloff et al., 1984) that phosphatidyl inositol might be a component of ice nuclei. The physical size of ice nucleation sites has been determined in situ, both in *P. syringae* and in *E. coli* expressing ice nucleation proteins, by gamma-ray inactivation analysis (Govindarajan and Lindow, 1988b). Nucleation sites are very large and show a logarithmic relationship between size and temperature at which they are active. For example, sizes of about 9 and 620 kDa correspond to nuclei that are active at or below -2°C and -9°C , respectively. The minimum mass of a functional ice nucleus, active only between -12 and -13°C , was about 150 kDa, which is in the size range of the ice protein monomer. Ice nuclei are predominantly associated with the outer bacterial membrane (Lindow et al., 1989), although aggregates that are not membrane-associated but contain ice nucleation protein are found in cells that overproduce the protein (Deininger et al., 1988; Wolber et al., 1986).

Ice nucleation protein monomers presumably associate with other such molecules and with lipids but little is known about the physicochemical nature of these associations. For example, chemical cross-linking experiments indicate that ice protein monomers have other such molecules as nearest neighbors (Govindarajan and Lindow, unpublished observations). The relationship between ice protein concentration (P) and ice nucleus activity per cell (N) in *E. coli* and *P. s. pv. phaseolicola* is nonlinear (Lindgren et al., 1989; Southworth et al., 1988). When activity is

measured at -9°C the activity of N increases according to the second power of P over a large range of values up to about 0.4 nuclei/cell. High-power relationships apply when N is measured at warmer temperatures.

Practical and research applications connected with ice nucleating *Pseudomonas* and the ice nucleation genes are discussed in detail in several reviews (Lindow, 1987; Lindow and Panopoulos, 1988; Warren, 1987), but a few representative examples may be mentioned briefly here. One is the use of nonviable Ina⁺ cells in snow-making technology for ski resorts. Another is the use of a promoterless ice nucleation gene as a sensitive "reporter" of bacterial gene expression (several hundred thousand-fold more sensitive than the conventional β -galactosidase reporter) (Lindgren et al., 1989). A third is the use of ice nucleation genes and/or proteins in diagnostic technology (Warren, 1987). Finally, site-directed deletion of the ice nucleation gene from epiphytically competent nonpathogenic strains of *P. syringae* and *P. fluorescens* ("ice-minus" and Frostban;rm, respectively) was used to generate prototype biological control agents of frost injury to plants, the first "genetically engineered" bacteria to be released outside the laboratory under Environmental Protection Agency (EPA) permit in the USA (Lindow and Panopoulos, 1988). Such strains are presumably free of outside mutations and thus permit more definitive analysis of bacterial interactions in the phylloplane (Lindow, 1987).

Habitats of Phytopathogenic and Related Plant-Associated Pseudomonads

Plant pathogenic and plant-associated pseudomonads are found in a multiplicity of environments. Crosse (1968) defined four categories of bacterial pathogens in relation to their principal habitat and mode of survival: 1) pathogens with no soil phase; 2) pathogens with a transitory or ephemeral soil phase; 3) pathogens with a protracted soil phase; and 4) those with a permanent soil phase. The different taxonomic groups of the bacterial pathogens fit well into these categories as there is a strong relationship between taxonomic groupings and the kinds of diseases they cause. There also is a good correlation between groupings and disease epidemiology (Schroth et al., 1978). The great majority of phytopathogenic pseudomonads are foliar pathogens. They do not survive long in soil if not associated with the host or host residues.

Pseudomonads constitute a substantial part of the microflora in the rhizosphere and rhizoplane

and some may on occasion cause some damage (Schippers et al., 1987; Suslow and Schroth, 1982). These pseudomonads are primarily saprophytes but are excellent competitors on plant parts. They also are commonly found in the endo-rhizospheres (Foster et al., 1983); such strains could be placed into Crosse's group 4.

Foliar Pathogens

The great majority of the foliar pathogens, approximately 50 or more when including pathovars and species, belong in habitats 1 and 2 (no soil phase or a transitory soil phase). Most of them are pathovars of *P. syringae*. As reviewed by Schroth et al. (1978) and Schuster and Coyne (1974), most foliar pathogens that have been studied have the capability of surviving in plant residues up to a year when the host plant is plowed under. However, the duration of time that the pathogen survives greatly depends on soil temperature and moisture. Few if any will survive long when the environment is warm and moist and ideal for decomposition of plant debris. Some pathogens appear to colonize plant roots for short periods of time (Schneider and Grogan, 1977). However, there is little evidence that any of these strictly foliar pathogens survive in soil when not associated with host tissues.

P. syringae and its many pathovars are closely associated with the living plant and the mechanisms of survival are ideal for perpetuation. For example, stone and pome fruit pathogens such as *P. syringae* pv. *syringae*, *P. s.* pv. *savastanoi* and *P. s.* pv. *morsprunorum* survive in lesions, cankers, tumors, or sometimes as leaf epiphytes. Therefore, there usually is available inoculum present for dissemination to infection courts when environmental conditions suitable for infection occur. There is a great amount of information available on the epiphytic activities of these and other foliar pathogens: *P. s.* pv. *syringae* (Ercolani et al., 1974; Lindow et al., 1988), *P. s.* pv. *savastanoi* (Ercolani et al., 1971; Wilson, 1935), *P. s.* pv. *lachrymans* (de Lange and Leben, 1971), *P. s.* pv. *glycinea* (Leben et al., 1968), *P. s.* pv. *persicae* (Gardan et al., 1972) and others (Leben, 1974). These bacteria in general can be characterized as follows: they have an epiphytic growth phase (Hirano and Upper, 1983), many are seed-borne, others maintain a permanent plant-associated relationship (epiphytic growth or incipient infections), and all can be disseminated by water, insects, and other animals. They cause blights, cancers, overgrowths, leaf and fruit spots, wilts, and rots (*P. viridiflava*). They are motile, which enhances survival by enabling them to explore large areas of the microenvironment (Leben et al., 1970) and to respond quickly

to favorable and unfavorable chemotactic stimuli (Barachini and Sherris, 1959; Cuppels, 1988; reference is not an exact match Kock, 1971; Smith and Doetsch, 1968). The importance of flagellar motility was shown by Panopoulos and Schroth (1974) using isogenic pairs of motile and nonmotile strains; twelve times as many lesions were caused by motile strains as compared to their nonmotile counterparts. There is no evidence that motility affects systemic activities.

Although foliar bacterial pathogens are disseminated by rain, much of the inoculum remains on leaves since it is not easily washed off plant surfaces. This presumably is related to the electrical charge of the cell surface. Factors affecting motility of pseudomonads have not received much attention. It generally is known that substances such as amino acids and carbohydrates serve as attractants (Chet et al., 1973).

Soil-Borne Pathogens

Only a relatively few bacterial pathogens can be placed into category 3 (diseases with a protracted soil phase). However, it is doubtful if most would survive long in fallow soil and there is little evidence that any of them compete well when colonizing residues or nonliving plant materials. Examples of soil-borne bacteria are the fluorescent pathogens *P. tolaasii*, *P. marginalis* (synonym *P. fluorescens* biovar 2) and *P. aeruginosa*, and the nonfluorescent pathogens *P. cepacia*, *P. gladioli* pv. *gladioli*, *P. gladioli* pv. *alliiicola*, *P. plantarii*, and *P. solanacearum*. *P. aeruginosa* is commonly isolated from soil (Green et al., 1974), and *P. marginalis* seems to be ubiquitous in soil and often as an internal resident of plant tissues. The latter bacterium has not been well defined taxonomically, nor has it been examined carefully as a plant pathogen. Disease appears to be triggered by conditions of high moisture such as when sprinkling lettuce. There also have not been comprehensive studies on *P. tolaasii* (mushroom disease) (Wong and Preece, 1979), *P. g.* pv. *gladioli*, and *P. g.* pv. *alliiicola*. There are a number of biovars and races of *P. solanacearum* as previously discussed, and they vary greatly with respect to the types of diseases they cause and modes of survival. Race 1, which infects solanaceous and other plants, appears to survive well in soil probably because of its ability to colonize roots of many plants. Race 2 (the banana and heliconia strains) does not survive long in soil (Buddenhagen, 1965).

Pathogens of Humans

P. aeruginosa and *P. cepacia* are interesting in that they are among the few plant pathogens that

have been implicated as causing diseases of both plants and animals. *P. aeruginosa* is an important nosocomial pathogen of humans (reference is not an exact match von Graevenitz, 1977) and is particularly significant in burn wards or when patients are compromised by other diseases such as cancer. It is a quasipathogen of plants (Cho et al., 1975; Green et al., 1974; Schroth et al., 1977), causing damage only when plants are subjected to stress such as high temperatures and moisture. Many strains isolated from plants and soil appear to be identical to a number of the major pyocin types of clinical origin (Kominos et al., 1972; Schroth et al., 1977). Lebeda et al. (1984), working with both plants and animals, concluded that both clinical and plant strains of *P. aeruginosa* were pathogenic for animals but not soil strains. There are only two cases where *P. aeruginosa* has caused a disease in the field and/or in storage; Cother et al. (1976) and Gupta et al. (1986) reported that the bacterium caused a severe case of onion bulb rot. However, others (Knösel and Nimitan, 1976) have questioned that *P. aeruginosa* is a cause of plant disease.

The dual role of *P. cepacia* as a plant and animal pathogen is not clear primarily because of the unsettled taxonomy reference is not an exact match Gonzales and Vidaver (1979) reported, from a study of a relatively few strains isolated from animals and plants, that they differed in a number of characteristics. It is important to know if these differences would be maintained if the study were done with a larger assemblage of strains. *P. cepacia* is a serious and common pathogen of onion (Kawamoto and Lorbeer, 1976). It also has been reported to be a common rhizosphere microorganism and has been used as a biocontrol agent against various fungal plant pathogens (Weller, 1988). With respect to humans, it causes serious diseases of compromised patients (Bassett et al., 1970; Bottone et al., 1975; Carson and Petersen, 1975; Ederer and Matsen, 1972; von Graevenitz, 1977), especially when it is a contaminate of fluids or substances that are injected into the bloodstream. The unsettled taxonomy of *P. cepacia* is another case that suffers from the general inactivity in the field of systematics.

Host Specialization

Many of the phytopathogenic pseudomonads have been characterized as having narrow host ranges. For example, most of the *P. syringae* pathovars were thought to attack only closely related species of plants. However, exceptions are known. Pathovar *tabaci* is reported (Kennedy and Tachibana, 1973) to cause a disease of both tobacco and soybean, some strains

of pv. *phaseolicola* infect both mulberry and soybean (Schroth et al., 1971), pv. *tomato* has been isolated from diseased stone fruits (Arsenijerik and Hildebrand, personal observations) and, as previously stated, *P. maculicola* and *P. antirrhini* can infect tomato (Hildebrand et al., 1984). *P. s. pv. syringae* has a large host range and is a common epiphyte on many plants.

There is no doubt some host specialization with pv. *syringae*, but this has not been well worked-out because of the enormity of the task, including the complex matter of defining pathogenicity, as discussed subsequently. Pathovar *syringae* strains associated with blights and blights of stone and pome fruits, citrus (Gross et al., 1977), legumes (Saad and Hagedorn, 1972), and various other plant hosts (Otta, 1974; Sands et al., 1977; Shane and Baumer, 1987; Smith and Mansfield, 1981; Surico and DeVay, 1981) appear to have some different pathological properties; for example, the legume strains are clearly host-specific and the citrus strains can be distinguished by certain phenotypic tests (Hildebrand, unpublished observations), the production of syringomycin and syringotoxin (Gonzalez et al., 1981), and both can be distinguished by southern hybridization and RFLP analysis (Hendson and Hildebrand, unpublished observations).

Host specialization has only been intensively studied with a few pathovars. *P. s. pv. phaseolicola*, the cause of halo blight of bean, was ideal for pathogenicity studies because of the ease of inoculating a large number of herbaceous plants and obtaining fast, relatively unequivocal results (Schroth et al., 1971). Pathovar *phaseolicola* attacks *Phaseolus vulgaris* L. (common bean), *P. limensis* Macf. (large-seeded lima bean), and *P. lunatus* f. *macrocarpus* (Benth.) Van Ess. (small-seeded lima bean), whereas the closely related pathogen *P. glycinea* attacks *Glycine max* (L.) Merr. (soybean). The diversity and plasticity of pathovars is exemplified by pathovars *phaseolicola* and *glycinea* in that a few strains of each pathovar attack the primary host of the other and both pathovars and *P. s. pv. mori* produce similar symptoms on lima bean.

P. viridiflava, *P. cichorii*, and *P. marginalis* appear to have broad host ranges (Fahy and Lloyd, 1983; Pieczarka and Lorbeer, 1975; Sampson and Hayward, 1971). These pathogens cause similar symptoms on a wide range of vegetables and appear to be favored by conditions of high moisture. *P. viridiflava* causes a watery rot of foliar parts of many plant such as tomato, peach, pumpkin, crucifers, and cowpea. *P. cichorii* is a common lettuce pathogen but has been found on chicory, endive, clover, cauliflower, poppy, celery, tobacco and other plants. The ill-defined *P. marginalis* has been attributed as the cause of various field and storage rots of

vegetables. None of these pathogens have been well-researched.

Pseudomonas solanacearum is a particularly interesting pathogen with respect to its ecological and pathological characteristics. Race 1 infects solanaceous and other plants, race 2 infects banana and heliconias, and race 3 infects potato. Each race consists of numerous known and unknown pathovars.

Pathogenicity Tests

Experienced phytobacteriologists generally have little problem in evaluating the potential of a pathogen to cause disease or in assessing virulence. However, this general area represents one of the greatest “pitfalls” in phytobacteriology. An understanding of the problems and errors in interpretation that often are associated with assessing host ranges and pathogenicities is critical. This affects decisions made by regulatory agencies, which in turn affect such activities as quarantines and microbial release policies. It also may have a major impact in formulating conclusions when making a molecular analysis of characteristics associated with virulence. The ability of many bacterial plant pathogens, particularly those causing foliar and wilt diseases, to cause an assortment of reactions on nonhost plants has contributed to many misunderstandings and erroneous claims with respect to host ranges and virulence. It frequently is overlooked when conducting plant pathogenicity tests that massive dosages of bacteria ($>10^7$) when injected into a plant with a syringe or other similar means will cause a necrotic hypersensitive response (Klement, 1963) and a variety of other reactions, depending upon the plant (Hildebrand et al., 1988). Massive inoculations of bacteria into nonhosts result in bacterial multiplication for a limited period of time (Ercolani and Crosse, 1966; reference is not an exact match Király et al., 1977) with the production of metabolites. This causes injury to the host manifested by a variety of symptoms. This type of host-solicited reaction should not be confused with those resulting from a true host-pathogen relationship. Such artificially contrived host responses do not occur normally in the field nor do the bacteria spread to other contiguous tissues as with a true disease. When in doubt about the validity of results from a pathogenicity test, it is recommended that the experiment be repeated using an inoculation technique that most closely simulates bacterial inoculation in nature. Thus, when working with a leafspotting bacterium, the leaves of plants should be sprayed gently with an inoculum of 10^5 to 10^7 and the plants placed in a moist chamber for 12–24 hrs to enable the bacteria to invade the stomates as they would in nature. Although this

is a greater dosage of bacteria than would be expected to occupy an infection court in nature, infections frequently do not occur with laboratory-grown inoculum at lesser densities.

Another commonly made error in conducting pathogenicity tests is to grow plants in unfavorable environments or under conditions that natural host resistance mechanisms are attenuated. For example, plants grown in greenhouses or growth chambers with inadequate lighting, or at abnormal temperatures, often lose their natural resistance to pathogens. Experimental designs that greatly favor multiplication of the pathogen, such as using detached plant parts or “compromising” the host, should be considered suspect. Under such conditions, pathogens often attack plants which normally would not be infected. In short, pathogenicity tests require the exercise of good judgement concerning the relevancy of the experimental design. Accordingly, some investigators have called for standardized inoculation tests. However, this is neither reasonable nor practical when considering the range of diseases and modes of pathogenesis.

Isolation of Phytopathogenic *Pseudomonads*

Experienced diagnosticians generally use relatively few media for isolating most bacterial plant pathogens. Most media used are not selective since highly selective media generally are somewhat toxic and the percentage recovery of cells is much less compared to standard rich media. In addition, selective media tend to discriminate for certain populations within a taxon since media frequently are designed without testing a broad representation of strains. Consequently, investigators often note that selective media are more useful in some geographical areas than others.

The choice of using a general medium such as King's medium B over a selective medium depends greatly upon the nature and condition of the isolation material. For example, it usually is not necessary to use selective media when isolating from lesions or diseased plant material if the infections are relatively fresh and secondary invaders have not colonized the tissues. With good material, the pathogen is usually the dominant bacterium on the isolation medium. Experienced workers become expert at recognizing bacterial plant pathogens by colony characteristics. When there is a question about identification, there are a number of relatively quick determinative tests that may be used as a check for authenticity. For example, the 30-second oxidase test (Hildebrand et al., 1988; Sands et al.,

1970) quickly differentiates between most fluorescent pseudomonads that cause foliar diseases and other fluorescent pseudomonads including all saprophytes which are oxidase positive. The one exception is the oxidase-positive, arginine dihydrolase-negative *P. cichorii*, which causes leaf spots of several plant species.

Selective media are helpful or necessary when isolating from plant residues, soil, or material when there are many other microorganisms present. Bacterial plant pathogens have relatively slow doubling times compared to many soil saprophytes and thus they are easily inhibited on rich media by faster growing bacteria (Hildebrand and Schroth, 1972).

For more detailed information on the various media that have been described for phytopathogenic bacteria including the determinative tests used to identify them, the reader is advised to consult Fahy and Persley (1983), Lelliott and Stead (1987), and Schaad (1988). We list here some media which are commonly used for isolating pseudomonads.

Isolation under Nonselective Conditions

King's medium B (King et al., 1954) is the preferred medium for isolation of bacterial plant pathogens because of its nondiscriminatory characteristics and since most fluorescent pseudomonads fluoresce on the medium. Even when the pathogen is suspected to belong to another genus, medium B still is used at least as one of the media, since most pathogens grow well on it and there is always the chance that the pathogen may indeed be a pseudomonad. Most commonly, several media may be used when isolating bacterial pathogens. Some pseudomonads such as *P. cepacia* and *P. gladioli* that do not fluoresce produce other distinctive pigments that help their identification. As previously noted, there are a few pseudomonads that fluoresce better on the media of Garibaldi (1967) and Luisetti et al. (1972) than on King's medium B.

King's Medium B for Nonselective Isolation and Pigment Production of *Pseudomonas* (King et al., 1954)

Proteose peptone No. 3 (Difco)	20.0 g
Glycerol	15.0 ml
K ₂ HPO ₄ (anhydrous)	1.5 g
MgSO ₄ · 7H ₂ O	1.5 g
Agar (Difco)	20.0 g
Distilled water	1.0 liter

Adjust pH to 7.2

Semi-Selective Media

M-71 Medium (Leben, 1972) for *P. syringae* pv. *glycinea* and Various Other Pathovars of this Group

Glucose	5.0 g
Peptone	10.0
Casein hydrolysate	1.0 g
Cycloheximide	0.05 g
Triphenyl tetrazolium HCL	0.05
Boric acid	1.0 g
Agar	20.0 g
Distilled water	1.0 liter

Although this medium was designed primarily for the soybean bacterial pathogen, it appears to work well for many other pathovars of the *P. syringae* group.

King's Medium B plus Cephalexin and Cycloheximide (KCB) (Mohan and Schaad, 1987) for Isolation of *P. syringae* pv. *syringae* and *P. s. pv. phaseolicola*

For KBC, the following ingredients are added to 900 ml of King's medium B (made with ingredients for a liter):

Boric acid, autoclaved 1.5% aqueous solution	100.0 ml
Cephalexin (stock solution of 10 mg/ml distilled water)	8.0 ml
Cycloheximide (stock solution of 100 mg/ml 75% methanol)	8.0 ml
Agar	16.0 g

Modification of Sucrose Peptone Medium (MSP) (Mohan and Schaad, 1987) for Isolation of *P. syringae* pv. *phaseolicola*

Sucrose	20.00 g
Peptone	5.00 g
K ₂ HPO ₄	0.50 g
MgSO ₄	0.25 g
Bromthymol blue (1.5% w/v in 20% ethanol)	1.00 ml
Agar	20.0 g
Distilled water	1.0 liter

Adjust pH to 7.2–7.4, autoclave and cool to 45°C, and then add:

Vancomycin (10 mg/ml aqueous solution)	1.0 ml
Cephalexin (stock solution of 10 mg/ml in water)	8.0 ml
Cycloheximide (stock solution of 25 mg/ml in 12.5% methanol)	8.0 ml

Acetamide Medium (Hedberg, 1969) for Isolation of *P. aeruginosa*

The following ingredients are added per 1 liter of water:

NaCl	5.0 g
MgSO ₄	0.2 g
NH ₄ H ₂ PO ₄	1.0 g
K ₂ HPO ₄	1.0 g
Acetamide	20.0 g
Agar	20.0 g

Final pH after autoclaving is 6.7

Acetamide medium is excellent for isolating *P. aeruginosa* from plant material and soil (Cho et al., 1975; Green et al., 1974), especially when incubating the cultures at 38°C. Enrichment broth for detecting small populations in soil is made by omitting the agar and incubating shake cultures at 38°C. After 3 days of incubation, an

aliquot of the suspension was plated on acetamide agar.

Trypan Blue Tetracycline (TBT) Medium (Hagedorn et al., 1987) for *P. cepacia*

Glucose	20.0 g
L-Asparagine	1.0 g
NaHCO ₃	1.0 g
KH ₂ PO ₄	500.0 mg
MgSO ₄ · 7H ₂ O	100.0 mg
Trypan Blue	50.0 mg
Tetracycline	20.0 mg
Agar	20.0 g
Distilled water	1.0 liter

pH was adjusted to 5.5 with 10% phosphoric acid (4 ml/liter). The tetracycline was filter-sterilized and added after autoclaving. For low soil dilutions it was recommended that crystal violet, 5 mg/l, and filter sterilized nystatin, 50 mg/l, be added.

Tetrazolium Chloride (TZC) Medium for Isolating *Pseudomonas solanacearum* (Kelman, 1954)

Peptone	10.0 g
Casein hydrolysate (Difco)	1.0 g
Glucose	5.0 g
Oxoid Agar No. 3	12.0 g
Distilled Water	1.0 liter

Adjust pH to approximately 7.0, autoclave, and add to the molten agar (approximately 55°C) filter-sterilized 1% 2, 3, 5-triphenyl tetrazolium chloride to give a final concentration of 0.005%. The medium is usually stored in small bottles for future use.

TPC medium is very good for differentiating virulent from avirulent mutants which readily occur in culture. The virulent wild type forms irregular to round, fluidal, white colonies with pink centers, in contrast to the common mutant which forms a round, butyrous, deep-red colony with a narrow, bluish border.

The Granada and Sequeira (1983) Modification to Improve Selectivity

Heat the TZC medium given above to 45° and add the following compounds per liter:

2, 3, 5-triphenyl tetrazolium chloride (as sterile 1% aqueous solution)	50 mg
Crystal violet	50 mg
Thimerosal (merthiolate)	5 mg
Polymyxin B sulfate	100 mg
Tyrosine	20 mg
Chloromycetin	5 mg
Cycloheximide (optional-to inhibit fungi)	50 mg
Chlorothalonil (optional-to inhibit fungi)	80 mg

The antibiotics and fungicides are sterilized by dissolving in 70% ethanol. The appearance of colonies is similar to TZC. Some strains of *P. solanacearum* are sensitive to chloromycetin and the concentrations need to be adjusted downward.

Other semi-selective media have been reported to be helpful for the following taxa: *P. glumae* (Tsushima et al., 1986), *P. pseudoalcaligenes* subsp. *konjaci* (Hayashi, 1987) *P. cepacia* (Burbage and Sassar, 1982), *P. cichorii* (Wu and

Thompson, 1984), and *P. s. pv. savastanoi* (Surico and Lavermicocca (1989). The CVP medium (Cuppels and Kelman, 1974; see also The Genus *Erwinia* in the second edition) also is helpful for identifying pectolytic pseudomonads such as *P. marginalis*.

Identification of Phytopathogenic Pseudomonads

Bacteriocin and Phage Relationships

Bacteriocins and phages have been useful in epidemiological studies and typing strains at the subspecific level. However, there are many problems associated with either technique because of absence of specificity. In addition, the techniques may be unreliable because of such factors as mutation of the host, mutation of the phage, and difficulty in defining host ranges (Okabe and Goto, 1963; Vidaver, 1976; Crosse and Garrett, 1963). The status and examples of research where phages and bacteriocins were used in the identification of various bacterial plant pathogens including *P. aeruginosa* were covered previously in *The Prokaryotes* (Schroth and Hildebrand, 1981). There has been little research in this area since then, primarily because of the development of more sophisticated techniques with greater powers of resolution. Methods using monoclonal antibodies, RFLP and genetic probes offer many advantages over past techniques. Epidemiological studies are frequently done with strains genetically marked for resistance to an antibiotic because of the ease with which large populations of a bacterial strain can be monitored.

Genetic Marking of Bacterial Strains

The method of choice for monitoring the population dynamics of bacterial strains, whether they are pseudomonads or belong to other genera, is to genetically mark them for resistance to an antibiotic (Kloepper and Schroth, 1981; Bahme and Schroth, 1987). The most frequently used antibiotic is rifampicin because relatively few bacteria in nature are resistant to it. Also, stable resistant strains can be readily isolated whereas resistance and stability of the resistance often appears to be a problem with many other antibiotics such as nalidixic acid.

Caution must be exercised when using genetic marking such as rifampicin because it appears to affect the ecological competence of the strains (Lewis et al., 1987). We have noted in our investigations that strains marked with rifampicin may lose some of their properties such as reduced antibiotic production and a slower doubling time after a period of time. However, at present there

are no better alternatives that are available for field use when making numerous samplings.

Serological Relationships

In the previous edition of *The Prokaryotes* (Schroth and Hildebrand, 1981), we detailed many examples where serology was used to discern relationships among the phytopathogenic pseudomonads. In general, serology complemented other techniques in confirming the identity of a strain. Serology was not widely used for identifying plant pathogenic bacteria because of lack of specificity of the antigenic components of the many *Pseudomonas* species and pathovars.

There have been great advances this past decade in the development of improved serological methods. The enzyme-linked immunosorbent technique (ELISA) and the specificity of monoclonal antibodies offer great potential for discerning strains and studying their epidemiology in nature. These new techniques have not yet been well exploited with the bacterial plant pathogens. However, there are some excellent examples of the usefulness of these techniques to identify strains with xanthomonads and fastidious bacterial plant pathogens (see Chapter 228).

Fatty Acid Composition of Whole Cells

Sasser and his colleagues (Roy, 1988; Sasser, 1988; Sasser and Miller, 1984) have developed a sophisticated chromatographic method with computer analysis to identify many bacterial plant pathogens. The equipment and software is very expensive. The method is based on the finding that as many as 50 different fatty acids may be present in a cell. Bacterial cells are harvested from agar plates and suspended in methanol and sodium hydroxide in tubes which are sealed and heated. The esters are extracted in a suitable solvent, separated from the aqueous phase, and subsequently separated by gas chromatography. A library of profiles from known strains are part of the software which enable a comparison with unknown bacteria. The method appears to have good resolution for some pathovars (Roy, 1988). There are no publications available which clearly define the potential of this method for distinguishing the many pathovars and species of *Pseudomonas*.

Preservation of Pseudomonad Cultures

Phytopathogenic and plant associated pseudomonads are typical bacteria that can be stored using conventional methods. Lyophilization

using skim milk or other menstrua works well. M. P. Starr successfully stored lyophils (skim milk as the menstruum) of pseudomonads for the International Collection of Phytopathogenic Bacteria (ICPB) for decades at room temperatures. Today, most investigators also freeze cultures at -70°C or in liquid nitrogen (-196°C) for convenience. This works well for the phytopathogenic bacteria (Sly, 1983). Loss of viability is much less at the low temperatures. Commonly used cryoprotectants are 5–15% glycerol or dimethyl-sulfoxide (DMSO). We use 15% glycerol in our work. There are no doubt differences in the ability of various pseudomonads to survive at these temperatures and in lyophils. However, there is no ready source of information available to guide investigators.

Some investigators store bacteria in broth and water cultures and maintain them at room temperatures. In general this is done by placing about 5 loopfuls of bacteria in 10 ml of a rich broth or water (DeVay, 1963). We have maintained many cultures up to seven or more years using these techniques. However, the occurrence of mutations is a problem. Mutations are also inevitable when cultures are maintained by mass transfers. Our recommendation is to immediately freeze bacteria of interest to reduce the occurrence of mutations.

Mutations occur to some extent regardless of the storage method that is used. Although many strains may maintain characteristics of interest such as pathogenicity, there often are subtle changes which are not detected. These become evident when strains are tested in the field because any mutation is likely to reduce the ecological competence of an organism. This is a common problem when laboratory stored strains are reintroduced into their natural environments for ecological investigations.

Xylophilus

ANN WILLEMS AND MONIQUE GILLIS

Introduction

Xylophilus is a genus of slow-growing, yellow-pigmented bacteria belonging to the family Comamonadaceae in the β subclass of the Proteobacteria. It comprises a single species, *Xylophilus ampelinus*, a phytopathogenic bacterium that, so far, has been isolated in different parts of the world only from diseased grapevines affected with bacterial necrosis and canker.

Phylogeny

Xylophilus ampelinus was shown, initially by DNA:rRNA hybridizations (De Vos and De Ley, 1983; Willems et al., 1987) and more recently by 16S rDNA sequence analysis (Wen et al., 1999) to belong to the Comamonadaceae family in the β subclass of the Proteobacteria. Its nearest phylogenetic neighbors are the other members of this family: the genera *Acidovorax*, *Brachymonas*, *Comamonas*, *Delftia*, *Hydrogenophaga*, *Polaromonas*, *Rhodoferax* and *Variovorax*, and several genera of misnamed *Aquaspirillum* species β (Figure 1). Of all these taxa, *Variovorax paradoxus*, a yellow-pigmented hydrogen-oxidizing bacterium, appears to have a somewhat closer relationship with *Xylophilus ampelinus*. The 16S rDNA sequence similarity of these taxa is 97.9%, but the bootstrap value is 87% and therefore it is not clear if this relationship is significant (Willems and Gillis, in press).

EMBL Accession number of the 16S rRNA gene of *Xylophilus ampelinus* ATCC 33914 sequence is AF078758.

Taxonomy

Xylophilus ampelinus was originally classified in the genus *Xanthomonas* because it is a Gram-negative, aerobic, nonsporeforming, rod-shaped, monotrichously flagellated, plant pathogenic bacterium that produces a yellow water-insoluble pigment and metabolizes sugars oxidatively (Panagopoulos, 1969). Later, several

reports (e.g., of pigment analysis); (Starr et al., 1977), comparative studies of the biosynthesis of aromatic amino acids (Byng et al., 1983; Whittaker et al., 1981), and DNA-rRNA hybridization studies (De Vos and De Ley, 1983) produced evidence showing that the grapevine pathogen was probably not a genuine *Xanthomonas* species (Bradbury, 1984). A polyphasic taxonomic study of more than 30 strains from different geographic origins by means of whole-cell protein analysis, numeric analysis of enzymatic features, DNA-DNA and DNA-rRNA hybridization, demonstrated that this organism indeed does not belong to *Xanthomonas*, but belongs in the so-called “acidovorans” rRNA complex, now known as the family Comamonadaceae in the β subclass of the Proteobacteria (Willems et al., 1991). Therefore the transfer of *Xanthomonas ampelina* to the new genus *Xylophilus* was proposed (Willems et al., 1987).

Habitat

Xylophilus ampelinus strains have been isolated exclusively from different cultivars of *Vitis vinifera* displaying symptoms of bacterial necrosis and canker. Their occurrence has been reported from various vine-growing regions of the world, including the Mediterranean area, the Canary Islands, Austria, Switzerland, Bulgaria, South Africa and Argentina.

Isolation

Xylophilus ampelinus can be isolated from grapevines affected by bacterial necrosis and canker. Isolation of strains may be complicated by the extremely slow and poor growth of *Xylophilus*, often permitting fast-growing saprophytes to overgrow isolation cultures (Panagopoulos, 1969).

Strains can be isolated throughout the year (Panagopoulos, 1969), although isolation from infected material collected in hot and dry periods may be difficult (Serfontein et al., 1997).

Fig. 1. Dendrogram obtained by neighbor-joining analysis of a distance matrix of 16S rDNA sequences, showing the position of *Xylophilus* among other members of the Comamonadaceae. Accession numbers are given in parentheses.

The most common isolation sources are small pieces of infected wood, taken aseptically from diseased vines and soaked for 20 minutes in sterile water. The resulting bacterial suspension is plated out onto nutrient agar (Panagopoulos, 1969; Erasmus et al., 1974; Grasso et al., 1979). After 5 to 6 days, small pale-yellow colonies will appear which, after 8 to 10 days, can attain a diameter of 0.4 to 0.6 mm (Panagopoulos, 1969). Isolation can be improved by incubating cuttings from diseased shoots that include a node, in closed plastic bags together with wet cotton plugs. After an incubation of 3 days in the dark at 15°C, extracts from the cuttings contained significantly more *Xylophilus ampelinus* bacteria than controls. This enrichment technique can also be applied to latently infected material without apparent signs of disease (Serfontein et al., 1997).

Identification

Most characteristic for *Xylophilus ampelinus* strains is their extremely slow and poor growth on most media at the optimal growth temperature of 24°C, and these features allow their differentiation from other yellow-pigmented species of the Comamonadaceae. The following features permit differentiation from *Xanthomonas* species: very low salt tolerance, absence of

gas production from most sugars, failure to hydrolyze gelatin and esculin, positive urease reaction, growth on Na, K-tartrate and on L-glutamic acid, absence of growth on sucrose, and use of L-glutamic acid as sole carbon and nitrogen source (Van den Mooter and Swings, 1990).

Differentiation of *Xylophilus ampelinus* from other slow-growing organisms occurring on grapevine is possible by Gram reaction, catalase and oxidase tests, urease production and lipolysis of Tween 80 (Serfontein et al., 1997). In phytopathology laboratories, serological tests with specific antisera are used for rapid identification of the pathogen (Erasmus et al., 1974; Ridé, 1996). A polymerase chain reaction (PCR) identification test using the specificity of the 16S–23S rDNA spacer sequence was reported (Serfontein et al., 1997) but not published in detail. The EMBL accession number for the spacer sequence is U76357.

Cultivation

Media

Xylophilus ampelinus grows rather slowly on most media. In general, the use of a large inoculum is required for good growth. Media should be prepared freshly as *Xylophilus ampelinus* strains fail to grow on media that have been

reheated or sterilized twice (Panagopoulos, 1969).

Strains grow rather poorly on nutrient agar, but this may be improved by the addition of 5% sucrose. Best growth is reported on yeast extract-galactose-calcium carbonate (YGC) medium (composition [w/v] 1% yeast extract, 2% galactose, 2% CaCO_3 , 2% agar; Panagopoulos, 1969; Bradbury, 1973). Good growth is also obtained on glucose-yeast extract-calcium carbonate-agar (GYCA), containing (w/v) 0.5% yeast extract, 1% glucose, 3% CaCO_3 and 2% agar (Willems et al., 1987). The presence of CaCO_3 in both these media prevents the transmission of light, and therefore colony morphology is more conveniently studied on yeast extract-galactose (YEGAL) medium (composition in g liter⁻¹: yeast extract, 5, galactose, 10, K_2HPO_4 , 3.01, NaH_2PO_4 , 4.55, NH_4Cl , 1, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.5, ferric ammonium citrate, 0.05, CaCl_2 , 0.005, distilled water, 1 liter; yeast extract and galactose, each dissolved in 100 ml, should be autoclaved separately as concentrated solutions; Starr et al., 1977).

Growth Conditions

Optimal growth temperature is 24°C, and minimum and maximum growth temperature are 6 and 30°C, respectively (Panagopoulos, 1969). On synthetic media, 0.1% glutamic acid is required as a growth factor (Panagopoulos, 1969; Bradbury, 1973).

Colony Morphology

On nutrient agar, colonies are round with entire margins, slightly raised, semitranslucent, pale yellow and glistening; colony diameters are 0.2 to 0.3 mm after 6 days (0.6 to 0.8 mm after 15 days). Growth is better on GYCA medium where colonies are yellow. The yellow pigments of *Xylophilus* are sensitive to potassium isobutoxide but are very hard to purify and therefore not yet studied (Starr et al., 1977).

Occasionally *Xylophilus* strains produce two stable colony types, one type with relatively large yellow colonies (diameter 0.8 to 2.0 mm after 15 days on GYCA) and the other smaller, paler colonies (0.4 to 1 mm after 15 days on GYCA). Microscopically, as well as by analysis of total protein extracts by SDS-PAGE and DNA-DNA hybridizations, both types are usually highly similar (Willems et al., 1987).

Preservation

Cultures that have been grown on screw-capped slants at 24°C for 2 to 3 days can be stored at 4°C,

caps tightly closed. They should be transferred at least every 2 months. For long-term preservation, strains can be lyophilized.

Physiology

Xylophilus ampelinus strains have a strictly chemoorganotrophic metabolism. They use only a limited number of carbohydrates, organic acids and amino acids for growth. Of a total of 60 substrates tested, growth was recorded only on D-glucose, D-galactose, L-glutamic acid, Na-succinate, Na-fumarate, K, Na-tartrate, Na-L-malate, Na_3 -citrate and Ca-gluconate (Van den Mooter and Swings, 1990).

Xylophilus strains generally show very little variation. Even isolates originating from different geographical regions showed highly similar whole-cell protein SDS-PAGE patterns and little variation in enzymatic features, as tested with API ZYM systems (Willems et al., 1987). However, considerable variation between different populations was reported for the use of glucose and tartaric acid and for tyrosinase activity (Ridé, 1996).

A variation of the Biolog™ GN system in which the recommended sucrose peptone agar was replaced by nutrient agar, has been used to characterize several strains, but of the 95 substrates tested, only acetic acid, propionic acid, L-aspartic acid, L-glutamic acid and L-pyroglutamic acid were oxidized (Serfontein et al., 1997).

The regulation mechanisms of aromatic amino acid biosynthesis involves inhibition of 3-deoxy-D-arabinoheptulonate-7-phosphate synthetase by tryptophan, chorismate, prephenate, phenylalanine, and tyrosine. Co^{2+} is needed for maximum activity. Prephenate dehydrogenase is NAD^+ specific and is not inhibited by tyrosine (Byng et al., 1983; Whitaker et al., 1981).

Epidemiology

Recognition of the Causal Agent of Bacterial Necrosis of Grapevine *Xylophilus ampelinus* causes bacterial necrosis and canker of grapevines and is responsible for important economic losses to viticulture in several parts of the world. The disease was first described in France in 1895 as "Maladie d'Oléron" (Ravaz, 1895), but the actual causal agent was not isolated until 1969.

In 1939, "Tsilik marasi," a disease of Cretan grapevines was reported and attributed to a fungus of the family Pythiaceae (Sarejanni, 1939). It was considered to be different from "Maladie d'Oléron" and "Gommose bacillaire" in France and from "Mal nero" in Italy. These three dis-

eases of grapevine and the similar “Vlamsiekte” in South Africa were at that time all attributed to *Erwinia vitivora* (Sarejanni, 1939; Du Plessis, 1940). Later this bacterium (syn. *Erwinia herbicola*, now *Pantoea agglomerans*) was shown to be an ordinary saprophyte, commonly isolated from infected plant material (Lelliott, 1974). In 1969, the isolation of a very slow growing, yellow-pigmented bacterium from grapevines with “Tsilik marasi” symptoms was reported. It was shown to be the causal agent of the grapevine disease and named *Xanthomonas ampelina* (Panagopoulos, 1969). It was then shown to be identical to the causal agent of “Maladie d’Oléron” (Prunier et al., 1970), “Vlamsiekte” (Erasmus et al., 1974) and “Mal nero” (Grasso et al., 1979).

Geographical Distribution

Xylophilus ampelinus has been isolated from diseased grapevine in Greece, France, Sardinia, Sicily, Spain and South Africa (Panagopoulos, 1969; Prunier et al., 1970; Garau et al., 1987; Grasso et al., 1979; López et al., 1987; Erasmus et al., 1974). Similar disease symptoms were reported from Argentina, Austria, Bulgaria, the Canary Islands, Portugal, Switzerland, Tunisia, Turkey, the former Yugoslavia and the former USSR (Bradbury, 1984; Panagopoulos, 1987). The actual distribution of the disease may be much larger because its symptoms can easily be confused with those attributed to other bacteria such as *Pseudomonas syringae* and *Erwinia vitivora* (now *Pantoea agglomerans*; (Panagopoulos, 1969).

Occurrence and Spreading of the Disease

Whereas bacterial necrosis and canker of grapevine was a rather rare disease at the beginning of the 20th century, it has since gained importance in the Mediterranean area through a combination of factors, including favorable local environmental conditions and agricultural practices, in particular increased mechanization of viticultural practices (Ridé, 1996). Inasmuch as *Xylophilus ampelinus* survives in the vascular tissue, transmission of the disease can easily occur via pruning lesions through the use of contaminated tools and infected grafting material. Wind and rain favor the spread of bacterial ooze from infected leaves, and severe winds and storms may cause wounds, thus providing additional access routes for the pathogen. Exceptionally dry seasons may result in the partial recovery of infected vineyards (Ridé, 1984; Panagopoulos, 1987; López et al., 1987).

Pathogenicity

Bacterial necrosis and canker of grapevine caused by *Xylophilus ampelinus* first becomes apparent in early spring, when buds on affected shoots fail to open. Typical symptoms include longitudinal cracks and cankers that develop from hyperplasiae in the cambial tissue. The underlying vascular tissue shows a brown discoloration and eventually will die. Other parts of the shoot, less severely affected, may survive. Symptoms may develop on petioles, flower and fruit stalks, causing death of leaves, flowers or fruits. Leaves infected through hydathodes or stomata show reddish brown lesions. Roots may also be infected, resulting in retarded growth of shoots. The severity of symptoms may vary considerably on different grapevine varieties (Panagopoulos, 1969; Ridé, 1984; Grasso et al., 1979; López et al., 1987; Ridé, 1996).

There is no effective cure available and treatment consists of removing and burning infected shoots or, in cases of severe infection, removing and burning the whole plant. When pruning, tools should be disinfected before moving from one plant to the next. The only preventive measure that has given some success is treatment with Bordeaux mixture. In severely affected regions, the use of resistant grapevine cultivars is advisable (Ridé, 1996). An in vitro test to assess cultivar susceptibility involves inoculation of 2-month-old plants (having 8 to 12 internodes) by decapitation with scissors dipped in a bacterial suspension. The number of internodes showing disease symptoms after several weeks of incubation provides an estimate for the progression of infection (Peros et al., 1995).

The Genus *Acinetobacter*

KEVIN TOWNER

Introduction

Gram-negative nonfermentative bacteria belonging to the genus *Acinetobacter* have been classified previously under at least 15 different names (Bergogne-Bérézin and Towner, 1996), and it is only relatively recently that rational taxonomic proposals have emerged. Delineation of species is still the subject of ongoing research, and a rapid and reliable method of assigning new isolates to individual species is particularly needed.

Notwithstanding the continuing taxonomic confusion, it is clear that acinetobacters are common, free-living saprophytes found in soil, water, sewage and foods. They are also ubiquitous organisms in the clinical environment, where they can be isolated as commensals from the skin of hospital staff and patients. They have increasingly been recognized as important nosocomial pathogens involved in outbreaks of hospital infection, particularly in high-dependency or intensive care units, where they rapidly develop resistance to even the most potent antimicrobials (Bergogne-Bérézin and Towner, 1996).

Although the significant pathogenic role of *Acinetobacter* is largely confined to nosocomial infections, it is important to note that these organisms are ubiquitous in both the clinical and nonclinical environments. Their metabolic versatility means that they may play an important role in a variety of commercially important industrial processes, as well as in the biodegradation of a wide range of environmental pollutants. While much remains to be learned about the lifestyles of the different members of the genus, it is clear that some facets of their behavior are unique and others provide new insights into prokaryotic behavior in general.

Members of the genus *Acinetobacter* have suffered a long history of extensive taxonomic change which has inhibited a proper appreciation and understanding of their significant biological properties and pathogenic importance. Although the delineation of species within the genus is still the subject of ongoing discussion and research, it appears that the current taxon-

omy should form a rational scientific foundation for the numerous important investigative studies required in the future.

Phylogeny

Members of the genus *Acinetobacter* have historically been classified by various authors under a variety of different names (Bergogne-Bérézin and Towner, 1996) and consequently, much of the early literature concerning this group of organisms is difficult to interpret owing to confusion over phylogeny and the lack of a widely accepted classification scheme. The genus *Acinetobacter*, as originally proposed in 1954, included a heterogeneous collection of nonmotile Gram-negative saprophytes that could be distinguished from other similar bacteria by their lack of pigmentation. The *Subcommittee on the Taxonomy of Moraxella and Allied Bacteria* subsequently proposed in 1971 that the genus *Acinetobacter* should include only the oxidase-negative strains, and this division has been supported by the use of transformation tests (Juni, 1978) that still form a good basis for inclusion of isolates in the genus.

{*Bergey's Manual of Systematic Bacteriology*} classified the genus *Acinetobacter* in the family *Neisseriaceae* (Juni, 1984), but more recent molecular taxonomic studies have resulted in the proposal that *Acinetobacter* should be classified in the new family *Moraxellaceae* (Rossau et al., 1991). This new family includes *Acinetobacter*, *Moraxella*, *Psychrobacter* and related organisms, and constitutes a discrete phyletic branch in superfamily II of the Proteobacteria on the basis of 16S rRNA studies and rDNA-DNA hybridization assays (van Landschoot et al., 1986; Rossau et al., 1989).

Taxonomy

Delineation of species within the genus *Acinetobacter* is still the subject of much research. Phenotypic identification of individual species is

complex and time-consuming (Gerner-Smidt et al., 1991). However, using the formal molecular definition (Wayne et al., 1987) of a microbial species — i.e., that a species should include strains of approximately 70% or greater DNA-DNA relatedness and 5°C or less divergence values (ΔT^m) — more than 20 separate genomic species (DNA-DNA homology groups) have been recognized within the genus by different research groups on the basis of DNA hybridization studies. Based on the taxonomic recommendation that only genomic groups readily distinguishable by phenotypic methods and containing more than 10 strains should be given names, seven *Acinetobacter* genomic species have been given formal species names (Table 1). Genomic species 1, 2, 3 and 13TU are closely related and are sometimes referred to as the *A. calcoaceticus*–*A. baumannii* complex for epidemiological purposes.

Certain genomic species were described independently by Bouvet and Jeanjean (1989) and Tjernberg and Ursing (1989a), and there are some minor discrepancies in the numbering systems. To avoid further confusion, it is current practice to add the suffix BJ or TU to denote the genomic species delineated by the two studies. In addition, many reports in the scientific literature have reported *Acinetobacter* isolates that cannot be identified with any of the formally recognized genomic species. One such isolate from the Venice lagoon has been given the species name *A. venetianus* by its discoverers Di Cello et al. (1997) and has been shown to belong to the same

genomic species as the industrially important strain RAG-1 (Vaneechoutte et al., 1999). Because many of the strains studied in DNA-DNA hybridization studies have been derived from hospital sources, and because the most common habitats of these organisms are soil and water, it seems clear that many naturally occurring genomic species of *Acinetobacter* have yet to be delineated and that the current taxonomic listing is incomplete (Nemec et al., 2000). Unfortunately, many reports of *Acinetobacter* in the scientific and medical literature still do not use the latest taxonomy or use inadequate identification methods. Although phenotypic identification is problematical, various molecular methods have been developed in an attempt to provide a rapid identification method suitable for routine taxonomic and epidemiological use.

Habitat

Certain acinetobacters are normal inhabitants of human skin, and members of the genus have increasingly been implicated as a presumed causal or contributory agent in numerous infectious disease processes. In addition to their occurrence in a range of clinical specimens (e.g., tracheal aspirates, blood and urine), acinetobacters can be readily isolated from moist skin areas, such as toe webs, the groin and the axilla. Other reservoirs of these organisms may include a range of both moist and dry surfaces and equipment within the hospital environment as well as

Table 1. Formally recognized genomic species of *Acinetobacter*.^a

Genomic species number	Genomic species name	Type strain
1	<i>Acinetobacter calcoaceticus</i>	ATCC 23055
2	<i>Acinetobacter baumannii</i>	CIP 70.34
3	Not named	ATCC 19004
13TU	Not named	ATCC 17903
4	<i>Acinetobacter haemolyticus</i>	ATCC 17906
5	<i>Acinetobacter junii</i>	ATCC 17908
6	Not named	ATCC 17979
7	<i>Acinetobacter johnsonii</i>	ATCC 17909
8	<i>Acinetobacter lwoffii</i>	ATCC 15309
9	Not named	ATCC 9957
10	Not named	ATCC 17924
11	Not named	ATCC 11171
12	<i>Acinetobacter radioresistens</i>	IAM 13186
13BJ	Not named	ATCC 17905
14	Not named	Bouvet 382
15BJ	Not named	Bouvet 240
15TU	Not named	Tjernberg 151a
16	Not named	ATCC 17988
17	Not named	Bouvet 942

^aNumerous published reports refer to *Acinetobacter* isolates that cannot be identified with any of the genomic species listed above. Such new isolates have not yet been formally grouped or given species names, although a newly named species, *Acinetobacter venetianus*, has been proposed (Di Cello et al., 1997).

the patients and staff (Bergogne-Bérézín and Towner, 1996).

Many studies within the genus *Acinetobacter* have been performed with clinical isolates. However, acinetobacters are also ubiquitous organisms in soil, water and sewage (Towner, 1996). It has been estimated that *Acinetobacter* may constitute as much as 0.001% of the total heterotrophic aerobic population of soil and water (Baumann, 1968). They have been found at densities exceeding 10^4 organisms per 100 ml in freshwater ecosystems and 10^6 organisms per 100 ml in raw sewage (LaCroix and Cabelli, 1982). They can be isolated from heavily polluted water, such as that found in wastewater treatment plants, but are found more frequently near the surface of fresh water and where fresh water flows into the sea (Droop and Jannasch, 1977).

Acinetobacters also are found in a variety of foodstuffs, including eviscerated chicken carcasses, various poultry and other meats, milk products and vegetables. It has been reported that acinetobacters constitute up to 22.7% of the total microflora of chicken carcasses. It is also known that acinetobacters are involved in the economically important spoilage of foods such as bacon, chicken, eggs and fish, even when stored under refrigerated conditions or following irradiation treatment (Towner, 1996).

It is worth noting that there is a significant population difference between the acinetobacters found in clinical and other environments. The vast majority of clinically significant isolates belong to the *A. calcoaceticus*–*A. baumannii* complex, whereas genomic species 7 (*A. johnsonii*), 8 (*A. lwoffii*) and 9 seem to predominate in foods and the environment. Other genomic species appear to comprise only minority components of the different populations investigated, but they may have evolved to acquire a selective advantage in as yet unrecognized specialized ecological niches.

Isolation

Isolation of members of the genus *Acinetobacter* can be accomplished using standard laboratory media such as trypticase soy agar or brain heart infusion agar. A differential medium such as MacConkey agar may be helpful in recognizing colonies of *Acinetobacter* on primary isolation. The optimum growth temperature for most strains is 33–35°C, but many clinically significant isolates will grow well at 37–42°C. In contrast, some environmental and food spoilage isolates have considerably lower optimum growth temperatures and may be unable to grow at 37°C.

Selective Enrichment

Most strains of *Acinetobacter* can grow in a simple mineral medium containing a single carbon and energy source such as acetate, lactate or pyruvate. An enrichment culture procedure for isolating members of the genus from soil and water has been described (Baumann, 1968). Liquid enrichment cultures containing 20 ml of medium (see below) are inoculated with a 5-ml sample of water, or a filtered 10% soil suspension, and vigorously aerated at either 30°C or room temperature. Cultures are examined microscopically after 24 or 48 h and streaked on to suitable isolation media. Strains of *Acinetobacter* have a slightly acid pH optimum for growth, and vigorous aeration at a pH of 5.5–6.0 favors their enrichment.

Baumann's Enrichment Medium

Sodium acetate (trihydrate)	2 g
KNO ₃	2 g
MgSO ₄ · 7H ₂ O	0.2 g

Dissolve in 0.04 M KH₂PO₄·Na₂HPO₄ buffer (pH 6.0), to a total volume of 1 liter.

It should be noted that the original recipe (Baumann, 1968) also contained a complex trace element supplement, but this addition is now rarely considered to be necessary as there are sufficient trace elements in the other medium components.

Differential Isolation on Solid Medium

Selective liquid enrichment is rarely used for isolation of *Acinetobacter* from clinical specimens. For clinical isolation, general purpose media such as blood agar or MacConkey agar are usually preferred because of their broad bacterial coverage, but in certain circumstances, it may be preferable to use a selective medium that suppresses the growth of other bacteria. Such a medium also can be used for plating out liquid enrichment cultures. An antibiotic-containing selective medium, Leeds *Acinetobacter* Medium (see below), has been found useful for the recovery of most *Acinetobacter* genomic species from clinical and environmental sources (Jawad et al., 1994).

Leeds *Acinetobacter* Medium

Bacteriological agar	15 g
Acid casein hydrolysate	15 g
Neutralized soy peptone	5 g
NaCl	5 g
D-(–) Fructose	5 g
Sucrose	5 g
D-Mannitol	5 g
L-Phenylalanine	1 g
Ferric ammonium citrate	0.4 g
Phenol red	0.02 g

Add ingredients to 1 liter of distilled water. Steam to dissolve ingredients. Mix well. Adjust pH of medium to 7.0. Autoclave for 15 min at 121°C and 15 lb/in². Cool to 50–55°C and then add the following ingredients (per liter): 10 mg of vancomycin, 15 mg of cefsulodin and 50 mg of cephadrine.

Mix well. Pour on plates. Pack in plastic bags and store at 4°C for up to 2 weeks.

Identification

Morphology

Short, plump, Gram-negative rods, typically 0.9–1.6 by 1.5–2.5 µm in the logarithmic phase of growth, but often becoming more coccoid in the stationary phase. The cell wall ultrastructure is typical of Gram-negative bacteria in general, but the cells are occasionally difficult to destain. Cells commonly occur in pairs, but also in chains of variable length. No spores are formed and flagellae are absent. Although generally considered to be nonmotile, “twitching” or “gliding” motility has been reported to occur, particularly on semisolid media. Many strains are encapsulated, and the capsule may be readily seen in India wet ink mounts. Colonies are usually nonpigmented, but some strains form white- to cream-colored colonies, which vary in consistency from butyrous to smooth and mucoid, and from 1–2 mm in diameter.

Phenotypic Identification

All members of the genus *Acinetobacter* are strict aerobes and can grow at a wide range of temperatures. Most strains will grow at 33°C, but some environmental isolates prefer incubation temperatures from 20–30°C. Clinical isolates of *Acinetobacter* will normally grow at 37°C and some strains can grow at 42°C. All acinetobacters are oxidase-negative and catalase-positive. The negative oxidase reaction serves to distinguish the genus from other related genera. Most strains of *Acinetobacter* can grow in a simple mineral medium containing a single carbon and energy source. A wide variety of organic compounds can be used as carbon sources by particular strains, although relatively few strains can use glucose. Most strains are unable to reduce nitrate to nitrite in the conventional nitrate reduction assay. A few clinical strains may show hemolysis on blood agar plates owing to the production of phospholipase C. Unlike other members of the *Moraxellaceae*, most strains are resistant to penicillin and many clinical isolates are resistant to cephalosporin antibiotics because of the overproduction of a chromosomal cephalosporinase.

There is no single biochemical test that enables ready differentiation of this genus from similar bacteria, but the nonfastidious nature and wide biochemical activities of the members of the genus makes them readily distinguishable from other bacteria at the genus level by the combination of nutritional tests applied to nonfastidious, nonfermentative organisms in general, including most commercially available diagnostic devices and systems. Phenotypic identification to the genomic species level is more problematic and time-consuming. A scheme of 22 phenotypic tests has been described that differentiates most of the genomic species known at the present time (Kämpfer et al., 1993), but this scheme is laborious and time-consuming. Most commercial rapid identification systems are inadequate for distinguishing the different genomic species, but promising results have been obtained with the automated Biolog system which involves the detection of oxidation with 95 different carbon sources (Dijkshoorn, 1996).

Serological Identification

A large number of capsular types have been identified by means of capsular reactions or immunofluorescence. This has resulted in the delineation of a large number of different serovars in two of the main genomic species (spp. 2 and 3) associated with infection in man (Traub and Leonhard, 1994). Inasmuch as all recently investigated lipopolysaccharide (LPS) molecules from clinical *Acinetobacter* isolates have been shown to be of the smooth phenotype, a serotyping scheme for identification of clinically important members of the genus may be possible (Pantophlet et al., 1998).

Genetic Identification

Members of the genus are themselves only rarely transformable, but can be easily identified by testing the ability of their isolated DNA to transform a nutritional or antibiotic resistance marker to the naturally competent strain BD413 originally isolated by Juni (1972). Transformation of this highly competent strain occurs readily, either on semisolid media or in liquid culture, and has been used as the basis of a test for the identification of *Acinetobacter* in clinical specimens (Brooks and Sodeman, 1974). The DNA samples from unrelated bacteria have consistently failed to transform the auxotrophic strain BD413 to prototrophy (Juni, 1972), and this test is consequently believed to allow unambiguous attribution of unknown strains to the *Acinetobacter* genus. There is currently no genetic test for the identification of individual genomic species.

Molecular Identification

A genus-specific 16S rDNA-targeted oligonucleotide probe has been used to recognize acinetobacters in general (Wagner et al., 1994). However, most work on the development of molecular methods has been dedicated to developing methods for distinguishing the individual genomic species. The "gold standard" method is DNA-DNA hybridization (Tjernberg et al., 1989b), but this technique is rather laborious and is normally used only in special situations in reference laboratories. Consequently, many research groups have concentrated on the development of alternative molecular methods for distinguishing individual genomic species. Unambiguous differences in rDNA sequences have been found in the highly variable regions of 16S rDNA molecules from at least 21 different genomic groups (Ibrahim et al., 1997), although the limited number of strains examined means that these findings cannot be relied upon for absolute identification of genomic species at the present time. It also should be noted that the groupings based on 16S rDNA analysis did not completely correlate with those based on DNA-DNA homology data. This is in contrast with an alternative strategy in which phylogenetic groupings were based on the nucleotide sequences of topoisomerase (*gyrB*) genes (Yamamoto and Harayama, 1996).

As an alternative to direct sequence-based identification, a range of more rapid molecular fingerprinting methods have been developed for distinguishing individual genomic species, with varying degrees of success. These methods can be divided into those based on structural features, such as outer-membrane protein patterns (Ino and Nishimura, 1989; Dijkshoorn et al., 1990), and those based on nucleic acid analysis. The most widely used techniques amongst the latter group include amplified fragment length polymorphism (AFLP) analysis (Janssen and Dijkshoorn, 1996), amplified rDNA restriction analysis (ARDRA; Vaneechoutte et al., 1995; Dijkshoorn et al., 1998), ribotyping (Gerner-Smidt, 1992), tDNA spacer fingerprinting (Ehrenstein et al., 1996) and 16S-23S spacer analysis (Dolzani et al., 1995).

Preservation

Cultures of *Acinetobacter* spp. can be stored for short periods (a few weeks) on nutrient agar slants kept at room temperature. It should be noted that many strains do not seem to survive for more than short periods in the refrigerator at 4°C. For long-term preservation, lyophilization should be used, or a heavy suspension of cells in brain heart infusion broth supplemented with

20% v/v glycerol can be frozen at -80°C. For regrowth, it is usually possible to simply streak out a loopful of the frozen stock without the necessity to thaw the entire suspension.

Physiology

The main identifying biochemical and physiological characteristics of the genus *Acinetobacter* have been discussed in the context of identification and only the most significant aspects are reiterated in this section. Early work on the metabolism of the genus has been comprehensively reviewed previously (Juni, 1978). Numerous subsequent papers describing enzymes, cofactors, metabolic pathways, products and other physiological aspects have confirmed that the *Acinetobacter* are strictly aerobic and broadly typical of other Gram-negative eubacteria, but with a number of distinctive physiological features that support the versatile lifestyle of this genus. It is worth emphasizing that many strains of *Acinetobacter* used in physiological studies were originally isolated in the 1970s or earlier and have never been properly identified to the genomic species level, and that many detailed physiological studies have been based on work with only one or a very limited number of strains.

Although rare strains of *Acinetobacter* showing growth factor requirements have been isolated, the vast majority of strains resemble saprophytic pseudomonads in being able to use any of a large range of organic compounds as a carbon and energy source in an otherwise mineral medium. Although the utilization of carbohydrates is relatively uncommon, the major biochemical feature of the genus is that many strains are able to metabolize a range of compounds including aliphatic alcohols, some amino acids, decarboxylic and fatty acids, unbranched hydrocarbons, sugars, and many relatively recalcitrant aromatic compounds such as benzoate, mandelate, *n*-hexadecane, cyclohexanol and 2,3-butanediol (Juni, 1978). Many such aromatic compounds are converted by acinetobacters to β -ketoadipate, which is degraded in turn to succinate and acetyl-CoA (it should, however, be noted that the precise spectrum of compounds degraded is frequently strain-specific). Members of the genus are therefore particularly suitable organisms for studying a variety of unusual biochemical pathways, and they also may have a role to play in degrading a range of pollutants and industrial products.

Central metabolism seems to be based on a Krebs tricarboxylic acid cycle, but with a rather unusual regulatory system in which AMP simultaneously modulates the activities of a number

of the constituent enzymes. This feature may act in a concerted manner to direct metabolic flux through the cycle, and such multipoint regulatory control may be a significant feature of energy metabolism in *Acinetobacter* spp. Numerous complex catabolic pathways feed into the tricarboxylic acid cycle, and various biosynthetic pathways, such as those involved in gluconeogenesis and amino acid synthesis, are subtly influenced by the need to integrate with the overall metabolism of the organism (Towner et al., 1991b). Most strains are unable to utilize glucose as a carbon source, but occasional rare strains are able to do so via the Entner-Doudoroff pathway. Many acinetobacters are, however, able to acidify media containing sugars, including glucose, via an aldose dehydrogenase. This property has previously been considered to be of major taxonomic significance in the subdivision of the genus, but DNA-DNA hybridization studies now suggest that this is not the case unless considered in combination with unrelated biochemical properties. Nevertheless, the property of glucose acidification is still sometimes useful for initial presumptive identification of the main genomic species (the *A. calcoaceticus*–*A. baumannii* complex) involved in human disease.

Although most strains of *Acinetobacter* are unable to reduce nitrate to nitrite in the conventional nitrate reduction assay, both nitrate and nitrite can be used as nitrogen sources by means of an assimilatory nitrate reductase. All acinetobacters are oxidase-negative, since they lack cytochrome *c*, but they do contain cytochromes *b*, *o* and occasionally *d* and *P-450* cytochrome.

One important difference from many organisms is that *Acinetobacter* cannot incorporate extracellular thymine or thymidine into DNA. Enzyme analysis has revealed that *Acinetobacter* lacks the enzymes thymidine phosphorylase, nucleoside deoxyribosyltransferase and thymidine kinase, but does contain enzymes for conversion of thymidine-5'-monophosphate to thymidine-5'-triphosphate. Polyphosphate has been shown to be accumulated by some acinetobacters in wastewater, and it has been suggested that these organisms could possibly remove inorganic phosphate from sewage in activated sludge. A high-affinity phosphate uptake system, inducible in the absence of inorganic phosphate (Kortstee et al., 1994), and a polyphosphate kinase induced by phosphate starvation (Geissdörfer et al., 1998) have both been demonstrated.

For further information on these and other biochemical pathways found in *Acinetobacter*, the interested reader should consult detailed reviews available elsewhere (Juni, 1978; Towner et al., 1991b; Towner et al., 1996).

Genetics

Modes of Gene Transfer

All three of the major modes of gene transfer are known to occur in *Acinetobacter*.

Transformation

The transfer of genetic material by transformation in a strain of *Acinetobacter* was first demonstrated in 1969 and forms the basis of the genetic test for the identification of members of the genus (Juni, 1972). Genetic competence for transformation seems to be a rare trait in *Acinetobacter* (Juni, 1978), and most transformation studies have been performed with the highly competent strain BD413. Studies of the conditions for quantitative transformation in strain BD413 have shown that competence occurs throughout the life cycle, but with a peak early in the exponential growth phase (Cruze et al., 1979). The highest transformation frequencies (0.5–0.7%) were obtained in an aspartate-containing medium which allowed the most rapid growth of BD413. Recipient cell concentrations of $1\text{--}6 \times 10^6$ cells per ml were found to give the highest transformation frequencies, regardless of the DNA concentration. Similar findings were reported with strain NCIB 8250 (Ahlquist et al., 1980), which seemed to have two peaks of competence, one during the early phase of batch culture and a second minor peak at the beginning of the stationary phase. The presence of cyclic AMP was found to increase the transformation frequencies obtained. Investigations into the basis for DNA uptake in competent strains of *Acinetobacter* have associated DNA uptake with components involved in assembly of the type IV pilus (Palmen and Hellingwerf, 1997; Link et al., 1998).

Nutritional and other markers (e.g., antibiotic resistance) are all transformed readily to competent strains. Early studies in the 1970s used transformation for preliminary genetic mapping of genes concerned with capsule biosynthesis, tryptophan biosynthesis and proline biosynthesis. More recently, catabolic pathways in *Acinetobacter* have been analyzed by natural transformation (Kloos et al., 1995), and the process has also been used to introduce randomly mutated genes into the chromosome of a competent recipient strain (Kok et al., 1997). Using previously isolated *Acinetobacter* genes modified to incorporate a *NotI* recognition sequence, the process of natural transformation has been exploited to generate a physical and genetic map of more than 40 genes on the circular c.3.8-kb chromosome of strain ADP1 (BD413UE; Gralton et al., 1997).

Transduction

A large number of bacteriophages active against specific strains of *Acinetobacter* have been isolated (Ackermann et al., 1994). Most *Acinetobacter* phages are lytic, but one temperate phage (P78) which lysogenizes its host strain and is capable of mediating generalized transduction has been isolated (Herman and Juni, 1974). Phage P78 is specific for its host strain and failed to lysogenize 389 other independently isolated strains of *Acinetobacter*, including the transformation-competent strain BD413. This narrow host specificity may be accounted for by the large number of different surface antigens found in this genus (Marcus et al., 1969). At present, neither P78 nor any other bacteriophage has been used for extensive genetic studies in *Acinetobacter*.

Conjugation

Conjugation in the genus *Acinetobacter* was first reported in 1976 in strain EBF65/65 (Towner and Vivian, 1976a). The broad-host-range plasmid RP4 was used as a vector and was found to be capable of mobilizing chromosomal genes between different mutant derivatives of EBF65/65. Transfer of the chromosome occurred at detectable frequencies only on solid surfaces (not in liquid matings) and mobilization occurred from at least two different chromosomal locations (Towner and Vivian, 1976b). Chromosomal transfer also has been shown to be mediated by the naturally occurring *Acinetobacter* plasmid pAV1 (Hinchliffe and Vivian, 1980). Little is known about the precise nature and events involved in mobilization of the chromosome by RP4 and pAV1, but these systems have been successfully used to map a number of different mutations on a circular chromosomal linkage group in strain EBF65/65 (Towner, 1978; Vivian, 1981; Vakeria et al., 1984). A range of plasmids belonging to different incompatibility groups are capable of transfer by conjugation to *Acinetobacter* from enteric bacteria, although not all are stably maintained or capable of subsequent rounds of transfer (Chopade et al., 1985).

Genetic Organization and Regulation

So far as the gross topological structure of the chromosome is concerned, it is known only that the chromosome of strains EBF65/65 and BD413 is circular. There is some preliminary evidence that *Acinetobacter* is more akin to *Pseudomonas* than enteric bacteria in that functionally related genes can be located at several different positions on the chromosome (Towner, 1978; Gralton et al., 1997).

In contrast, knowledge of the fine structure of certain specific regions of the chromosome is quite well advanced for the highly competent *Acinetobacter* strain BD413. Particular attention has focused on the organization and regulation of genes concerned with the tryptophan biosynthetic and the β -ketoadipate degradative pathways. Striking similarities exist between the individual genes from *Acinetobacter* spp. and *Pseudomonas* spp. in these pathways, but considerable gene rearrangements seem to have occurred during the evolutionary process. Although the complete regulatory circuits for the tryptophan biosynthetic pathway have yet to be fully resolved in *Acinetobacter*, studies of the β -ketoadipate pathway have indicated that *Acinetobacter* strain BD4 exhibits induction patterns unlike those found in *Pseudomonas* spp. However, an important characteristic shared with *Pseudomonas* is that genes for physiologically interdependent steps in the β -ketoadipate degradative pathway tend to be linked together in supra-operonic clusters, a feature that may have important regulatory implications. Mapping and regulatory studies on these and related pathways in strain BD413 continue to be published regularly in the scientific literature. Detailed information on the formative studies can be found in previously published review articles (Haspel et al., 1991; Ornston and Neidle, 1991).

Plasmids

Several studies have reported that more than 80% of *Acinetobacter* isolates carry multiple indigenous plasmids of variable molecular size (Gerner-Smidt et al., 1989; Seifert et al., 1994), although other studies have reported problems in isolating plasmid DNA from *Acinetobacter* spp., often because of unappreciated difficulties in lysing the cell wall of these organisms. Most indigenous plasmids from *Acinetobacter* seem to be relatively small (<23 kb), and therefore probably lack conjugative functions.

As with many other groups of organisms, interest has focused particularly on plasmids associated with resistance to antibiotics. Although many clinical isolates of *Acinetobacter* show widespread and increasing resistance to a whole range of antibiotics, few studies have demonstrated plasmid-mediated transfer of resistance genes. This may partly reflect a lack of conjugative functions on indigenous plasmids, but also may reflect the absence of a suitable test system for detecting such transfer. For historical reasons, attempts to transfer plasmids from clinical isolates of any Gram-negative species have tended to use *Escherichia coli* K12 as a recipient strain. Complex and varied transfer frequencies

of standard plasmids belonging to different incompatibility groups have been observed between *E. coli* K12 and *Acinetobacter* strain EBF 65/65, and a number of these plasmids required an additional mobilizing plasmid for retransfer to occur (Chopade et al., 1985). Accordingly, it is not surprising that most reported cases of indigenous transmissible antibiotic resistance from *Acinetobacter* have been associated with plasmids belonging to broad host-range incompatibility groups (Towner, 1991a).

Apart from antibiotic resistance, genes encoding resistance to heavy metals (Kholodii et al., 1993) and important metabolic steps in the degradation of organic compounds and environmental pollutants, such as polychlorinated biphenyls (PCBs), have been shown to be carried on plasmids in *Acinetobacter* (Towner, 1991a; Fujii et al., 1997). Studies to date indicate clearly that though there is a pool of plasmid-mediated genetic information that is confined largely to *Acinetobacter*, a group of plasmids can cross the boundaries between *Acinetobacter* and other distinct genetic pools.

A range of cloning and shuttle vectors for in-vitro genetic manipulation experiments in *Acinetobacter* have been described (Ditta et al., 1985; Singer et al., 1986; Hunger et al., 1990; Gutnick et al., 1991; Minas and Gutnick, 1993).

Transposons and Integrations

Transposons probably play an important role in ensuring that particular novel genes can become established in a new gene pool, even if the plasmid vectors that transferred them are unstable. There have been several reports of chromosomally located transposons carrying multiple antibiotic resistance genes in clinical isolates of *Acinetobacter* (Towner, 1991a). In general, such transposons closely resemble those found in other Gram-negative bacteria. Transposons also have been used in conjunction with suicide plasmid vectors to introduce mutations to the *Acinetobacter* chromosome (Towner, 1991a; Leahy et al., 1993).

Integrations are conserved genetic elements which encode a site-specific recombination system that enables the insertion, deletion and rearrangement of discrete genetic cassettes within the integron structure (Stokes and Hall, 1989). Most, but not all, cassettes identified to date have been associated with antibiotic resistance, and large numbers of clinical isolates of *Acinetobacter* have been shown to carry integrons incorporated into their chromosome (Gonzalez et al., 1998; Seward and Towner, 1999; Gallego and Towner, 2001). It is clear that clinical isolates of *Acinetobacter* seem to share resis-

tance mechanisms with many other genera, and it has been suggested that integron structures make an important contribution to the dissemination of antibiotic resistance genes in the clinical setting.

Ecology

Species of Clinical Importance

In addition to carriage by patients and staff, various strains of *Acinetobacter* can be isolated from a wide range of both moist and dry inanimate sources in the hospital environment, including formica table tops, dust, ventilatory equipment, humidifiers, mattresses, urinals and wash basins. Numerous studies have now supported the observation that *A. baumannii* and its close relatives are the main genomic species associated with outbreaks of hospital infection. Thus, a typical study of 584 *Acinetobacter* isolates from 420 patients at 12 different hospitals over a 12-month period identified 426 (72.9%) strains as *A. baumannii* (Seifert et al., 1993). This large study also identified 158 isolates as belonging to species other than *A. baumannii*, of which the most common were *Acinetobacter* sp. 3 (55 isolates), *A. johnsonii* (29 isolates) and *A. lwoffii* (21 isolates).

Very little is known about the clinical significance of other *Acinetobacter* genomic species and further detailed investigations are required. The ubiquitous occurrence of acinetobacters in the environment, and as commensals on human skin, means that such isolates in clinical specimens are often considered to be contaminants. Diagnosis of infection with "unusual" *Acinetobacter* genomic species therefore often depends on clinical indications and repeated isolation of the same strain from a single patient. *Acinetobacter* spp. 3 and 13TU have often been implicated in documented outbreaks of infection involving nosocomial spread, whereas *A. junii* and *A. johnsonii* have been associated with point-source outbreaks. It is worth re-emphasising the close relationship between genomic species 1, 2, 3 and 13TU. This "*A. calcoaceticus*-*A. baumannii* complex" contains isolates that are mostly glucose-acidifying. The majority of glucose-negative, nonhemolytic strains found in clinical specimens seem to be identified mainly as *A. lwoffii*, *A. johnsonii* or *Acinetobacter* sp. 12, and it seems that these species are natural inhabitants of human skin. Most of the hemolytic isolates are identified as *A. haemolyticus* or *Acinetobacter* sp. 6. Other groups seem to be implicated only occasionally in human infections (Bergogne-Bérézin and Towner, 1996).

Species from the Environment

Acinetobacters are ubiquitous organisms that can be obtained easily from soil, food, water and sewage with appropriate enrichment techniques, but surprisingly few studies exist in which *Acinetobacter* isolates from environmental sources have been grouped according to the latest taxonomic criteria.

So far as food isolates are concerned, a study of 170 *Acinetobacter* isolates from various food sources (including fresh and spoiled meat and fish, vegetables, raw milk and cheese) demonstrated a clear difference in the distribution of genomic species between food and clinical isolates (Gennari and Lombardi, 1993), with *A. lwoffii* and *A. johnsonii* predominating in foods. The ubiquitous occurrence of *A. johnsonii* in the environment has also been demonstrated in several studies of polyphosphate-accumulating acinetobacters found in wastewater treatment plants (Kämpfer et al., 1992; Knight et al., 1993).

It therefore appears that there is a significant population difference between the acinetobacters found in clinical and other environments. Each population appears to be characterized by predominant groups of genomic species — spp. 2 (*A. baumannii*) and 3 in clinical environments, and spp. 7 (*A. johnsonii*) and 8/9 (*A. lwoffii*) in other environments. Other genomic species appear to constitute only minority components of the different populations. Some genetic interchange between populations is clearly possible for those groups that are capable of growing at both 37°C and lower environmental temperatures, and this fact may have implications for the spread of antibiotic resistance and metabolic genes.

Epidemiology

Human Carriage

At least 25% of healthy individuals may carry acinetobacters as part of their normal skin flora, but carriage of *Acinetobacter* spp. by healthy subjects at other body sites is normally low (Bergogne-Bérézin and Towner, 1996). In contrast, high colonization rates of the skin, throat, respiratory tract or digestive tract of hospitalized patients with clinically significant strains have been reported during outbreaks of infection, with infections involving mechanically ventilated intensive care unit (ICU) patients being associated particularly with a high colonization rate of the respiratory tract. Such patients often have heavy skin colonization, which probably contributes to the spread and persistence of outbreaks via the hands of hospital staff during trivial contacts (Bergogne-Bérézin and Towner, 1996).

From a clinical viewpoint, the isolation of strains belonging to genomic species 1, 2, 3 or 13TU in environmental cross-infection studies should be considered to be of greater epidemiological significance than the detection of genomic species associated mostly with nonhuman sources. The observed discrepancies in carriage rates between hospitalized patients and the normal population suggest that infecting or colonizing organisms in hospitals may be derived more often from cross-transmission or hospital environmental sources than from endogenous sources (e.g., the intestinal and digestive tract of the patients themselves). Differentiation of colonization from infection is not always easy, and many isolates, particularly from the skin, should be considered as colonizing rather than infecting organisms. However, the skin, respiratory tract and superficial wounds also should be considered as potentially important reservoirs of infecting organisms during outbreak situations (Bergogne-Bérézin and Towner, 1996).

Environmental Persistence

Acinetobacter spp. spread easily in the environment of infected or colonized patients, and can persist in that environment for many days or weeks, even in dry conditions on particles and dust. Air contamination is relatively rare, except in the immediate vicinity of infected or colonized patients, but numerous studies have documented the isolation of acinetobacters from various hospital equipment and surfaces (e.g., respirators, air humidifiers, mattresses, pillows, bedside cabinets and cupboards, telephones, door handles, patient charts, floors, washcloths, etc.; Bergogne-Bérézin and Towner, 1996). Survival in the environment is probably helped by the ability of *Acinetobacter* spp. to resist drying (Jawad et al., 1996) and to grow at a range of different temperatures and pH values (Bergogne-Bérézin and Towner, 1996). The population differences found between “clinically significant” and “environmental” isolates means that it is important to identify isolates to the genomic species level and type them (Dijkshoorn, 1996) before any firm epidemiological conclusions can be reached.

Disease

Bacteria belonging to the genus *Acinetobacter* are now recognized as increasingly important opportunistic pathogens causing a wide spectrum of nosocomial infection. Although acinetobacters are generally regarded as relatively low-grade pathogens, they can cause occasional severe infection, predominantly pneumonia,

particularly in immunocompromised patients who have undergone major surgery or trauma, or those with severe underlying disease (e.g., burns, immunosuppression and malignancy). Other opportunistic infections reported include septicemia, endocarditis, meningitis, skin and wound sepsis, and urinary tract infection. Although these organisms are associated primarily with nosocomial infection, some cases of community-acquired infection have also been reported (Bergogne-Bérézin and Towner, 1996).

One of the main reasons for disease caused by *Acinetobacter* is the fact that clinical isolates of these bacteria are frequently multiply resistant to the major antibiotics used to treat nosocomial infection. Widespread resistance to the major groups of antibiotics, particularly following the recent emergence of resistance to the carbapenem antibiotics, means that *Acinetobacter* infections are difficult to treat successfully, even with combination therapy. Indeed, the extensive use of antibiotics in hospitals probably alters the normal flora and actually results in the selection of resistant strains of *Acinetobacter*. Combined with their capacity for long-term survival in the hospital environment, this makes control of outbreaks of hospital infection caused by *Acinetobacter* one of the most difficult challenges faced by infection control teams.

Applications

A number of patent applications incorporating these organisms in various industrial processes have been awarded. An important advantage is that acinetobacters are easy to isolate, cultivate and manipulate genetically in the laboratory.

Pollution Control

The general biochemical versatility of members of the genus has resulted in *Acinetobacter* spp. receiving considerable attention as possible industrial microorganisms. In particular, the normal soil and water habitats of many strains, combined with their ability to degrade a wide range of organic compounds, has suggested that acinetobacters can be used for bioremediation of numerous hazardous and unpleasant waste and residue pollutant compounds produced as by-products of commercial processes. Thus, aromatic compounds which are toxic to most microorganisms, such as salicylate, halogenated aromatics and phenol, are capable of being degraded by acinetobacters (Schirmer et al., 1997). In many cases, total degradation occurs by the synergic action of complex microbial communities in which acinetobacters form an impor-

tant component. Certain acinetobacters are capable of elaborating and excreting polymers (of which the most well-studied is a polyanionic, cell-associated, heteropolysaccharide termed "emulsan" produced by strain RAG-1) that emulsify hydrocarbons, such as oils (Foght et al., 1989), thus making these substrates available for degradation in an aqueous environment (Gutnick et al., 1991; Navon-Venezia et al., 1995; Barkay et al., 1999).

A more controversial area concerns the ability of acinetobacters to remove phosphate from wastewaters. Phosphate removal from wastewater to minimize the problem of eutrophication is an important feature of sewage treatment plants. It can be shown in the laboratory that certain strains of *Acinetobacter* can accumulate polyphosphates, and examination of activated sludge samples from sewage treatment plants has shown that acinetobacters form a significant part of the constituent microflora. It has therefore been postulated that acinetobacters could form the basis of an inexpensive biological method for the direct removal of phosphate from wastewater, but their precise role (and its feasibility) in such a process remains a matter of some debate.

Biopolymers and Biosurfactants

Apart from its use in the degradation of oil, emulsan has a whole range of potential applications in the petroleum industry, including viscosity reduction during pipeline transport following formation of heavy oil:water emulsions, and production of fuel oil:water emulsions for direct combustion. The affinity of purified emulsan for the oil:water interface also has implications for the stability of oil emulsions during transport and storage, and also for their biodegradability following accidental spillage (Gutnick et al., 1991). In addition, U.S. Patent No. 4,619,825, filed on behalf of the Colgate-Palmolive Company, describes the use of emulsan-containing formulations for either mouthwash or toothpaste which have the effect of significantly reducing dental plaque formation and enhancing anti-carries activity.

A second important polysaccharide produced by a strain of *Acinetobacter* has been shown to bind to inorganic materials such as calcium carbonate (limestone). This polysaccharide has been termed "biodispersan" (Rosenberg et al., 1988) and is capable of dispersing limestone in water. Because limestone is used in a wide range of industrial processes, purified biodispersan is considered to have potential applications in manufacturing processes producing common products such as paper, paints and ceramics. A further bioemulsifying polysaccharide, termed "alasan," is produced by *Acinetobacter radiore-*

Table 2. Suggested applications for *Acinetobacter* spp. and their products.

Bioremediation of waste waters and effluents
Phosphate removal
Degradation of petrochemicals
Breakdown of organic pollutants
Production of biopolymers and biosurfactants
For prevention of dental plaque
For use in paper-making and other industries
For efficient emulsification of oil waste pollutants
For incorporation in cosmetics, detergents and shampoos
Biomass production
Single cell protein production
Manganese leaching from ores
Production of immune adjuvants
Clinical uses
Production of glutaminase-asparaginase
Production of L(-) carnitine

From Towner (1996).

sistens strain KA53 (Navon-Venezia et al., 1995; Navon-Venezia et al., 1998; Barkay et al., 1999).

Some other suggested uses for *Acinetobacter* spp. and their products are summarized in Table 2 and have been reviewed elsewhere (Towner, 1996).

The Family Azotobacteraceae

JAN HENDRIK BECKING

The family Azotobacteraceae is represented by two genera, *Azotobacter* (Beijerinck, 1901a, 1901b) and *Azomonas* (Winogradsky, 1938). The removal of the genera *Beijerinckia* and *Derxia* from the Azotobacteraceae was based on rRNA cistron analysis (De Smedt et al., 1980) and rRNA cistron similarities as observed in DNA-rRNA hybridization experiments (De Vos et al., 1985). Such experiments showed that *Beijerinckia* and *Derxia* are not closely related to the genera *Azotobacter* and *Azomonas*, but that they belong to other subdivisions or groups, i.e., the alpha and the beta subclasses, respectively of the Proteobacteria (see The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition). On the other hand, investigations on rRNA similarities of various gram-negative bacteria based on $t_{m(e)}$ values of dna-rRNA hybrids showed that *Azotobacter* and *Azomonas* are closely related to one another and to the *Pseudomonas fluorescens* rRNA branch. The latter branch or group belongs to the Superfamily I in the nomenclature of De Ley and coworkers (see The Proteobacteria: Ribosomal RNA Cistron Similarities and Bacterial Taxonomy in the second edition; De Smedt et al., 1980; and De Vos et al., 1985) or the gamma group/subdivision or subclass of the purple bacteria as defined by Woese et al. (1985a, 1985b) or the Proteobacteria, as defined by Stackebrandt et al. 1988.

Members of the Azotobacteraceae are primarily characterized as nonsymbiotic (i.e., free-living), aerobic, heterotrophic bacteria whose main property is the ability to fix molecular (atmospheric) nitrogen in a nitrogen-free or nitrogen-poor medium with an organic carbon compound (preferentially sugars, alcohols, or organic acids) as energy source. However, dinitrogen fixation is not unique to this family, as this property can be observed in quite a number of other unrelated bacteria (see The Genera *Azospirillum* and *Herbaspirillum* along with The Rhizobia in the second edition). Moreover, some representatives of this family can produce associative growth

(which is different from symbiotic growth) with higher plants. For these reasons, representatives of this family are usually called nonsymbiotic nitrogen-fixers.

General Habitats

Representatives of the Azotobacteraceae are regular inhabitants of soil, including aerially transported dust, of water habitats, and of plant surfaces such as the external environment of roots (rhizosphere) and leaves (phyllosphere). *Azotobacter chroococcum* and *A. vinelandii* also occur in marine habitats. Some species occur in much larger numbers in the rhizosphere of higher plants than in the soil itself, and it has been shown in some cases that this associative growth is beneficial for the plant because fixed nitrogen becomes available to the plant (Döbereiner, 1966, reference is not an exact match 1968). Some investigators (see “Applications”) report the same for *Azotobacter chroococcum* and a number of agricultural crops in India.

For *Azotobacter paspali* and the grass *Paspalum notatum*, the association seems to be species-specific (Döbereiner, 1966, 1970). Also, on leaf surfaces, members of this group (especially, *Azotobacter chroococcum*) often occur as nonpathogenic epiphytic flora, particularly on older or aged leaves. The bacteria probably proliferate at the expense of the sugar-rich and nitrogen-poor exudates of the plant; the exudates act as a kind of enrichment medium (see below). For the phyllosphere, it has been suggested that the fixed nitrogen becomes available to the plant (Ruinen, 1961), but an unambiguous proof using $^{15}\text{N}_2$ has not yet been presented.

Most species of this family occur in soil as well in water, but two *Azomonas* species, *A. agilis* and *A. insignis*, have so far only been isolated from water habitats. The pH value of the soil or water environment often governs the occurrence of a certain species. Therefore, the pH of the medium, in combination with selective carbohydrate utilization, are important factors for selective isolation of the various species in enrichment media.

Fig. 1. *Azotobacter chroococcum*. Thin section through cells demonstrating the presence of large, poly- β -hydroxybutyrate globules as reserve material. Many cells occur in pairs in the so-called diplococcus stage. Transmission electron micrograph. Bar = 0.5 μ m.

General Identification

Morphological and physiological properties are both very important for the identification of *Azotobacteraceae*. All representatives have the ability to fix nitrogen in simple media. Cells are usually large, blunt to oval in shape, 2 μ m or more in diameter. The morphology may change with various growth conditions. The cells are normally in pairs, but single cells or short chains may also occur. Motile by peritrichous or polar flagella or nonmotile. Intracellular poly- β -hydroxybutyrate is produced (Fig. 1). Cells are Gram-negative to Gram-variable (rarely). Endospores are not formed. Microcysts are formed in one genus (*Azotobacter*). They are chemoheterotrophic, preferentially utilizing sugars, alcohols, and salts of organic acids. Cultures are obligately aerobic and catalase-positive. They fix molecular nitrogen in a nitrogen-free or nitrogen-poor medium in air, but also under reduced oxygen pressure. Organic growth factors are not required. Trace elements (e.g., molybdenum or vanadium) are required because they are involved in nitrogenase activity. Normally, cells fix 10 mg of nitrogen per g of a suitable carbohydrate (usually glucose) in synthetic media containing 1–2% carbohydrate. However, the efficiency of dinitrogen fixation can be markedly increased (sometimes doubled up to 20–25 mg N/g carbohydrate) by lowering the carbohydrate levels (Becking, 1971), to levels such as usually occur in soils, or when under low oxygen tension (Meyerhof and Burk, 1928; J. H. Becking, unpub-

lished observations; see also “Physiological and Biochemical Aspects”).

They can utilize various sources of combined nitrogen, but some species utilize nitrate poorly or not at all. Water-insoluble and water-soluble pigments or fluorescent pigments are produced by some species.

In the genus *Azotobacter*, microcysts are formed in older cultures grown with sugar as carbon source. In some species, a medium containing butan-1-ol as organic substrate (0.1–0.2 ml is added prior to pouring of the agar plates) enhances cyst formation (Tchan and New, 1984). A microcyst can be distinguished from an endospore by its characteristic structure: a central body surrounded by a cyst coat, consisting of an exocystorium and an exine. In contrast to a spore, the cell inside the cyst is similar to the vegetative form and there are no cytological changes in the cell prior to its germination (Socolofsky and Wyss, 1961; Tchan et al., 1962). The primary habitat is soil, water, and the plant rhizosphere and phyllosphere. In this family, the GC content of the DNA ranges from 52–67.5 mol%. The type genus is *Azotobacter* (Beijerinck 1901b, 567).

Differentiation from Other Nitrogen-Fixing Bacteria

Although some rhizobia may fix nitrogen non-symbiotically, unlike *Azotobacter*, they can only do so under reduced oxygen tension. Furthermore, their cells are generally smaller than *Azotobacter* cells (*A. paspali* excepted). Moreover rhizobia need a more complex medium (supplemented with growth substances, etc.) for growth. Other nonsymbiotic nitrogen-fixing organisms have a different cell morphology and widely different physiological and nutritional requirements depending on the taxonomic group of the Prokaryote class to which they belong.

Genus Differentiation of Azotobacteraceae

Azotobacter: Microcysts formed; GC content is 63–67.5 mol% (T_m).

Azomonas: Microcysts not formed; GC content is 52–59 mol% (T_m).

Isolation

Species of the *Azotobacteraceae* are typical aerobic, chemoheterotrophic, dinitrogen-fixing bacteria. Therefore, any medium of suitable pH value that contains an organic carbon source, minerals (especially phosphate), some trace ele-

ments (in particular, molybdenum and/or vanadium), and no combined nitrogen is suitable for enrichment, since only organisms that can grow at the expense of atmospheric nitrogen are able to develop.

Members of this group fix dinitrogen better at low oxygen tension, probably because fixation is a reductive process (i.e., nitrogenase is inhibited or inactivated by oxygen). However, in enrichment cultures, care should be taken to provide sufficient aeration of the medium, in order to suppress the development of anaerobic or facultatively anaerobic bacteria (evident by a characteristic butyric acid smell of the enrichment culture), which may develop when the oxygen pressure is low or when the oxygen is totally exhausted. Therefore, thin-liquid layers in Erlenmeyer flasks or petri dishes are recommended to allow sufficient oxygen access. This precaution is not absolutely obligatory for enrichment of most *Azotobacter* species, since in static culture, they usually form a pellicle on the liquid surface. It is advisable to leave this pellicle undisturbed, because careless handling or shaking of the enrichment culture may rupture the pellicle and cause the cells to precipitate as a sediment, which stimulates the development of the above-mentioned anaerobic or facultative anaerobic contaminating bacteria always present in enrichment cultures.

General Enrichment Procedures

Members of the family Azotobacteraceae can be enriched from soil or water by adding phosphate (0.1%) and an organic carbon source, usually 1–2% sugar or a calcium (or sodium) salt of an organic acid, to one of the above substrates as will be described below. Usually, an organic carbon source and phosphate are the minimum nutrients that must be added to obtain the development of Azotobacteraceae under natural conditions in soil or water. Using this principle, a number of simple enrichment procedures can be designed for the successful isolation of members of this group.

ISOLATION OF AZOTOBACTERACEAE BY THE SOIL-PASTE PLATE METHOD A small amount of soil (about 30–50 g) is mixed in a porcelain mortar with about 0.5–1.0 g of organic carbon (e.g., sucrose, glucose, or mannitol), about 0.5 g of chalk (CaCO_3) to assure an alkaline reaction, 4 drops (0.12 ml) of a 10% aqueous K_2HPO_4 solution, and 4 drops of a 10% aqueous MgSO_4 solution. When the water content of the soil is low, some extra distilled water is also added in order to obtain a soil paste. If the soil is too sandy, or is difficult to make into paste for other reasons, sterile clay mineral (kaolinite) is added. The soil paste is transferred with a sterile knife point or

spatula to a small, low-rimmed container, watch glass, or hollow gypsum block, and the soil is firmly pressed into the hollow surface. With the aid of a knife or spatula, preferentially sterile, the surface of the soil is neatly smoothed. The small container with the soil is subsequently placed in a petri dish containing a wet piece of filter paper and incubated at 27–30°C. Care should be taken that the top of the soil does not touch the upper lid of the petri dish, thus causing anaerobic conditions. After 3–7 days incubation, glistening, slimy *Azotobacter* colonies develop on the smooth soil surface. Colonies of *A. chroococcum* turn brown in a few days.

ISOLATION OF AZOTOBACTERACEAE BY THE SIEVED-SOIL PLATE METHOD In this method (Winogradsky, 1932), silica-gel plates are prepared by treating a sodium-silicate solution with acid to have a complete inorganic substrate. The plates are impregnated with nitrogen-free, carbohydrate-containing nutrient solution suitable for the cultivation of Azotobacteraceae. Before impregnation, the excess salt (NaCl , when HCl is used for gel preparation) is washed out in running tap water, and then the plates are rinsed with sterile, distilled water. The solid medium is allowed to dry in an incubator. Subsequently, the plates are impregnated with medium, the superfluous medium is poured off, and the remaining water is evaporated in an incubator. The dry plates are seeded with soil crumbs; sieved soil is used preferentially (either sieved directly over the plate or distributed on the plate with a spatula) in order to obtain small soil particles and an even distribution. After incubation at 27–30°C, colonies of members of soil-inhabiting Azotobacteraceae develop on the gel around the soil particles.

The preparation of silica gel is rather laborious, but good quality agar can also be used, i.e., agar low in combined nitrogen. Other agars can also be made sufficiently low in combined nitrogen by some preparations, i.e., by fermentation of the agar in distilled water and by repeated removal and renewal of the rinsing solution. The treated agar (10–20 g/l) can be made up with Azotobacteraceae nitrogen-free medium (see below), and the nutrient agar plates inoculated with sieved soil particles in the manner mentioned above for the silica plates. As Azotobacteraceae medium, Winogradsky's nitrogen-free medium can be used. It has the following composition (g/l): KH_2PO_4 50.0; $\text{MgSO}_4 \cdot 7 \text{H}_2\text{O}$, 25.0; NaCl , 25.0; $\text{FeSO}_4 \cdot 7 \text{H}_2\text{O}$, 1.0; $\text{Na}_2\text{MoO}_4 \cdot 2 \text{H}_2\text{O}$, 1.0; and $\text{MnSO}_4 \cdot 4 \text{H}_2\text{O}$, 1.0; the pH is adjusted to 7.2 with NaOH . This is a stock solution, which can be stored indefinitely at room temperature; the medium is prepared by using 5.0 ml of stock solution and 0.1 g CaCO_3 per liter of distilled water (see Tchan and New, 1984). The medium

is sterilized at 120°C for 20 min. The organic substrate (10–20 g/l) is added to this organic medium. Some sugars, including glucose, must be sterilized separately before addition to the sterilized mineral medium. The medium is usually solidified with 15.0 g agar/per liter.

ISOLATION OF AZOTOBACTERACEAE BY THE NUTRIENT SOLUTION METHOD A complete nutrient medium is used (see e.g., Winogradsky's nitrogen-free mineral medium supplemented with a carbohydrate source as mentioned above). This medium is preferably sterilized in order to eliminate contamination from other sources. The liquid medium is usually placed in shallow layers in Erlenmeyer flasks or in petri dishes, and about 0.3–0.5 g of wet soil of the sample to be tested is used to inoculate 100–150 ml of enrichment medium.

For the investigation of distribution of members of Azotobacteraceae in water samples, usually an organic carbon source (5–20 g/l) is added to the water sample itself. Sometimes the sample is supplemented with some inorganic nutrients (particularly phosphate and molybdenum). The water sample can also be mixed with an equal volume of sterile nutrient solution of double strength. These two methods, in general, gave better results than the inoculation of a complete medium with a small amount of the water sample (e.g., 1–5 ml water sample added to 100–150 ml medium), probably because of the lower density of Azotobacteraceae in normal natural water sources compared to soil.

As already mentioned with use of nutrient solutions, the depth of the liquid layer employed should not be too high; if the liquid layers are too thick, anaerobic conditions may occur at the bottom of the flasks, resulting in growth of contaminants which inhibit the growth of Azotobacteraceae.

Representatives of the Genus *Azotobacter*

These are soil, water, plant rhizosphere, and phyllosphere organisms; therefore, all these substrates can be used as inoculum. Many members of this genus produce copious amounts of capsular slime (polysaccharide). No endospores are formed, but some form thick-walled microcysts, which, unlike spores, are encysted vegetative cells without cytological changes prior to their germination. The cells show motility by peritrichous flagella (Fig. 2) or they are nonmotile. The cells are Gram-negative. Although some species appear to be Gram-variable (e.g., Jensen and Peterson, 1954; Kirakosyan and Melkonyan, 1964; Norris and Kingham, 1968; Johnstone,

Fig. 2. *Azotobacter chroococcum*. Two cells in a pair ("diplococcus" stage) showing peritrichous flagella. Preparation shadowed with an alloy of gold and manganese. Transmission electron micrograph. Bar = 2.0 μ m.

1974), but Thompson and Skerman (1979) attribute these results to incomplete decolorization of thick smears.

Identification of *Azotobacter* Species

Cells are motile in *Azotobacter chroococcum*, *A. vinelandii*, *A. armeniacus*, and *A. paspali*, but motility is absent in *A. beijerickii* and *A. nigricans*.

Nonmotile variants have been described in *A. vinelandii*.

Excretion of water-soluble, yellow-green, fluorescent pigment occurs in *A. vinelandii* and *A. paspali* and that of red-violet or brownish-black pigment in *A. nigricans*, *A. armeniacus*, and sometimes *A. paspali* under certain conditions.

Rhamnose as the sole source of carbon can only be utilized by *A. vinelandii* and not by any other species. For a list of other specific carbon compounds and inhibitory substances, see the specific enrichment media given below for the various species.

Azotobacter chroococcum

Cells of *A. chroococcum* are pleiomorphic, bluntly rod-, oval-ovoid-, or coccus-shaped. Mean dimensions are 3.0–7.0 μ m long \times 1.5–2.3 μ m wide. The cell shape changes dramatically in time or with changes in growth (medium) conditions. Cells are often in pairs. Young cells are motile by peritrichous flagella. Microcysts and capsular slime are formed. Colonies are moderately slimy, turning black or black-brown on aging. The pigment produced is not water-diffusible.

SOIL-PASTE METHOD FOR ISOLATION OF *AZOTOBACTER CHROOCOCCUM* The soil-paste method described under the general techniques is a quick and easy method to obtain this species from soil. Also the sieved-soil plate method and the nutrient solution method are adequate for obtaining *A. chroococcum* from soil. Apparently, because *A. chroococcum* is the most common and predominant *Azotobacter* in soil, no special enrichment techniques are necessary to make it selectively dominant.

NUTRIENT SOLUTION FOR ISOLATION OF *AZOTOBACTER CHROOCOCCUM* The nutrient solution method, originally described by Beijerinck (1901a, 1901b) for the isolation of *A. chroococcum*, is also a good and well-established method for enrichment and isolation of *A. chroococcum* from soil and water samples.

Nutrient Solution Method

To a 500-ml Erlenmeyer flask, about 100 ml of nitrogen-free nutrient solution of the following composition is added:

Distilled water	1 liter
Glucose	20.0 g
CaCO ₃	20.0 g
K ₂ HPO ₄	1.0 g
MgSO ₄ ·7H ₂ O	0.5 g

Adjust to pH 7.2–7.6.

In some cases it is advisable to also add trace elements, especially molybdenum (NaMoO₄·2 H₂O, 0.005 g/l), to the medium. The medium is inoculated with about 0.3–0.5 g of soil; for water samples, the distilled water of the prescription is replaced by the surface water tested. After 1–3 days, an *Azotobacter* pellicle forms on the liquid surface.

Due to anaerobic conditions below the pellicle, nitrogen-fixing butyric acid bacteria (e.g., *Clostridium pasteurianum*) may develop later at the bottom of the flask, and eventually throughout the medium. It is therefore advisable to subculture the *Azotobacter* pellicle according to the normal procedures (by applying appropriate dilutions in sterile tap water) as soon as possible to nitrogen-free agar plates in order to reduce contamination. Such subculturing is also advisable because combined nitrogen produced by *Azotobacter* development may make it possible for non-dinitrogen-fixing contaminants to develop.

The following agar medium can be used for the isolation, purification, and further subcultivation of *Azotobacter chroococcum* found in the enrichment cultures:

Agar Medium for *Azotobacter chroococcum*

Distilled water	1 liter
Glucose	20.0 g
K ₂ HPO ₄	0.8 g
KH ₂ PO ₄	0.2 g
MgSO ₄ ·7H ₂ O	0.5 g
FeCl ₃ ·6H ₂ O	0.10 g (or 0.05 g)
CaCl ₂ ·2H ₂ O	0.05 g

or CaCO ₃	20.0 g
NaMoO ₄ ·2H ₂ O	0.05 g
Agar	20.0 g
Adjust to pH 7.4–7.6.	

With CaCl₂, the agar medium is translucent; with CaCO₃ it is opaque white. The latter substance is, however, in some cases an advantage for detecting *Azotobacter* colonies, because they do not produce acid on it. Acid-producing colonies, as evident by the dissolution of the calcium carbonate around the colony, are certainly not *Azotobacter* species. A further advantage for adding CaCO₃ to the medium is that it has a good buffering capacity at the alkaline side; an alkaline reaction is necessary for the development of *Azotobacter chroococcum*.

The presence of *A. chroococcum* in soil or water is strongly governed by the pH value of these substrates. In an environment below pH 6.0, *Azotobacter* is generally rare or totally absent (see Becking, 1961). H. L. Jensen (1965) tested 264 Danish soils and found that practically all of the soils above pH 7.5 contained *Azotobacter* (predominantly *A. chroococcum*) varying in numbers between 10² and 10⁴ per gram of soil. Of the 148 tropical soils tested by Becking (1961), all soils above pH 7.5 (pH range 7.5–9.0) contained *Azotobacter* (also mainly *A. chroococcum*) and, in the pH ranges of 7.0–7.4, 6.5–6.9, and 6.0–6.4, the percentage of *Azotobacter*-positive soils was 89, 57, and 32%, respectively. In nitrogen-free nutrient media, the lower pH limit for growth of *A. chroococcum* strains in pure culture is between pH 5.5 and 6.0 (Jensen and Petersen, 1955).

As already mentioned earlier (Becking, 1962), according to the author's experience, not all *Azotobacter* strains that produce a brown or brown-black pigment on aging (Fig. 3) belong to one species, because *Azotobacter chroococcum* strains are very pleomorphic (see Fig. 4). It was therefore likely that this species comprises a more complex group consisting of several species, whose delimitations have not yet been sorted out. The latter is confirmed by Thompson and Skerman (1979) who examined 151 strains of Azotobacteraceae of different provenance in 230 variant tests and analyzed the data according to numerical methods in a hierarchical classification of groups. They obtained evidence that at least two distinct black-brown-pigmented *Azotobacter* species occur next to *A. chroococcum*, i.e., *A. nigricans* and *A. armeniacus* (see below).

Azotobacter nigricans

This species, originally isolated by Krasil'nikov (1949), possesses, in contrast to *A. chroococcum* (but like strains of *A. beijerinckii*), nonmotile

Fig. 3. *Azotobacter chroococcum* cells. Four different strains of the same age growing on an identical medium (nitrogen-free, mineral glucose agar with 2% calcium carbonate). Note the presence of lipid-filled cells, cysts, and germinating cysts in some of the strains. Living preparations; phase contrast micrographs. Bar = 10 μ m.

Fig. 4. *Azotobacter chroococcum* colonies. Strains growing on the same medium (nitrogen-free, mineral glucose agar with calcium carbonate) and of the same age, showing the variation of the chromogenesis of the colonies. Bar = 1 cm.

cells. Cells are bluntly rounded rods in shape, occurring singly or in pairs. Mean cell dimensions are 4.1–4.9 μ m long \times 1.5–2.7 μ m wide. Moreover, they differ from *A. chroococcum* in a number of nutritional properties, such as the inability to utilize ethanol, pentan-1-ol, propionate, caproate, and benzoate and to produce brown-black or red-violet diffusible pigments. They differ from *Azotobacter armeniacus* by the inability to utilize caprylate, which compound can be used as carbon source by the latter species. In *A. nigricans*, the production of agar-diffusible homopolysaccharides from sucrose or raffinose is strain variable, but no strain produces any colony-retained homopolysaccharide. On aging, colonies of *A. nigricans* turn black-brown due to the same diffusible pigment, but a variant formerly called *A. beierinckii* subsp. *achromogenes* Jensen and Petersen 1954, but now proposed to be *A. nigricans* subsp. *achromogenes* (Thompson and Skerman, 1979) produces only a yellow non-diffusible pigment within the colony and no diffusible pigment.

Strains of this species has been isolated from European soils, particularly from East European soils.

There is no species-specific selective enrichment method for isolating *A. nigricans*.

Azotobacter armeniacus

This is a poorly understood species that has been described by Thompson and Skerman (1981). Cells are bluntly rounded rods, occurring singly or in pairs. Mean cell dimensions are 5.0–5.7 μ m \times 1.7–2.0 μ m. Strains of this species differ from *A. nigricans* by having motile cells, but they have in common with the latter species the production of a diffusible brown-black or red-violet pigment into the medium. In contrast to *A. nigricans*, they are able to use citrate or D-galacturonate as sole carbon source and most strains also can use *n*-valerate and caprylate, but like *A. nigricans*,

capronate is not utilized. All *Azotobacter* species, including *A. nigricans*, can utilize ammonium and nitrate as sole source of nitrogen, and these N-sources are assimilated in preference to molecular nitrogen, *A. armeniacus* is unable to use ammonium, nitrate, or glutamate as sole source of nitrogen for growth (Thompson and Skerman, 1979).

There is no special enrichment medium for *A. armeniacus*, but probably it can be enriched with caprylate as sole source of carbon, but *A. vinelandii* also can be grown on this medium. Further isolation, however, will differentiate between these two species.

Azotobacter beijerinckii

Formerly, this organism was not regarded as a distinct species, but merely as a nonpigmented variant of *A. chroococcum*. In the eighth edition of *Bergey's Manual* (Buchanan and Gibbons, 1974), it has, however, been restored to the species level. Cells are bluntly ended rods or ellipsoidal, occurring singly or in pairs, sometimes in short chains. Mean cell dimensions are 3.2–5.3 μm long \times 1.7–2.7 μm wide.

The main differences between *Azotobacter beijerinckii* and *A. chroococcum* are that colonies of *A. beijerinckii* produce, on aging, a yellowish or cinnamon pigment (in *A. chroococcum*, it is brown or blackish-brown) and its cells are nonmotile (motile in *A. chroococcum*). Moreover, it invariably lacks the ability (in contrast to *A. chroococcum*) to utilize starch as the sole source of carbon. Sometimes the inability to utilize mannitol is also mentioned as a determinative character (see Johnstone, 1974), but 9 out of 10 strains tested by Jensen and Petersen (1955) showed good growth on this carbon source. Thompson and Skerman (1979) mentioned in addition, that caproate is utilized by *A. chroococcum*, but not by its satellite species, *A. nigricans* and *A. armeniacus*. The differences between *A. nigricans*, which is also a species with nonmotile cells, and *A. beijerinckii* are not so clear with respect to carbon source utilization, except that malonate is used by all strains of *A. beijerinckii*, but only by a minority of strains of *A. nigricans*, and that D-glucuronate, D-galacturonate, and benzoate are utilized by *A. beijerinckii* but not by *A. nigricans* (Thompson and Skerman, 1979). The main difference remaining is the pigment, which in *A. nigricans* is black-brown to red-violet, whereas the excretion of any water-soluble pigment into the substrate is completely absent in *A. beijerinckii*. The physiological differences between *A. chroococcum* and *A. nigricans* or *A. armeniacus* are already outlined under the headings of the latter two species.

Tchan (1953) described a variant of *A. beijerinckii*, named *A. beijerinckii* subsp. *acidotolerans*, which could grow and fix dinitrogen at a pH of 4.75. Later, Tchan and New (1984) delineated this characteristic more in detail and distinguished two subgroups. An acid-tolerant subgroup and another subgroup distinguished by its sensitivity to 0.05% phenol or 40 $\mu\text{g}/\text{ml}$ diamond fuchsin, its inability to utilize sorbitol or aconitate, and its failure to produce diffusible homopolysaccharides. V. Jensen and Petersen (1954) have also described another form of *A. beijerinckii*, *A. beijerinckii* subsp. *achromogenes*, in which under the cultural conditions applied, no pigment ever was produced. The latter strains were isolated from Danish calcareous forest soils in a survey including all types of Danish soils (see later).

Jensen and Petersen (1954) also showed that acid tolerance is a rather common characteristic of *A. beijerinckii*, since all strains isolated could grow and fix dinitrogen to a pH of 5.1. The nitrogen-fixation data published by Jensen and Petersen (1955) showed, however, that considerably more atmospheric nitrogen was fixed under alkaline than under acidic conditions.

For selective enrichment of *A. beijerinckii* and elimination of *A. chroococcum*, a selective nitrogen-free medium of the same composition as used for *A. chroococcum*, but with CaCl_2 (instead of CaCO_3) and with a slightly acid pH (pH 4.9–5.5), can be employed. So far, no experience has been gained with such a medium since all *A. beijerinckii* strains so far known are casual isolates coming from *A. chroococcum* plates. It might be surmised that *A. beijerinckii* would favor somewhat acidic soils. In this respect it is remarkable that, in the above-mentioned survey of Danish forest soils by V. Jensen and Petersen (1954), *A. beijerinckii* was found predominantly in soil samples of two localities with beech (*Fagus sylvatica*) forest on calcareous soil with pH values of 7.0–8.0 and 7.8–8.0, respectively. In these and nearly all other forest soils tested, *A. chroococcum* was absent or nearly absent. These observations indicate that some calcareous forest soils are a favorable and probably selective habitat for *A. beijerinckii* and that the occurrence of *A. chroococcum* is confined to the more alkaline agricultural soils.

Azotobacter vinelandii

Cells are rounded-ended rods, occurring singly or in pairs. Mean cell dimensions are 3.0–4.5 μm long \times 1.5–2.4 μm wide (Fig. 5). Cells are motile with numerous peritrichous flagella; very rarely, some are nonmotile. Colonies are nonpigmented. They excrete a yellow-green, fluorescent, water-soluble pigment into medium.

Fig. 5. *Azotobacter vinelandii* cells. Three different strains growing on the same medium (nitrogen-free, mineral glucose agar) showing some variation in the cell size of the strains and in the number of lipid-filled cells, cysts, and germinating cysts. Living preparation, phase contrast micrographs. Bar = 10 μ m.

Fewer strains of *Azotobacter vinelandii* have been isolated in comparison with strains of *A. chroococcum* and *A. beijerinckii*. Most of the strains were casual isolates obtained from soil, such as the original strain of Lipman (1903a) from New Jersey (USA) soil (pH unknown). Wilson's strain O(P), used for many physiological and biochemical studies (e.g., Wilson and Knight, 1947; Shutter and Wilson, 1955), is probably a subculture of this strain. Bortels (1930) isolated another strain from German soil (originally described as *Azotobacter agile*), and Winogradsky (1932) obtained one strain from soil in France. Later, Winogradsky (1938) also underlined the relative rarity of this species.

The present author has obtained a number of strains—often in association with *A. chroococcum*—from Dutch soil, but also from freshwater samples using the nutrient solution method for

A. chroococcum (preferentially with ethanol as carbon source) for enrichment (J. H. Becking, unpublished observations). *A. vinelandii* was obtained mostly from rather alkaline Dutch and European soils, such as calcareous soils and soil derived from marine sediments, sea sludge, or sea muds that had been pumped up for leveling land. The latter soils, usually also rather rich in sodium chloride, showed pH values of 8.0–9.5.

The water samples from which this organism was obtained were pond, lake, or marsh water of alkaline reaction (pH 7.5–8.0). This species was also numerous in some tropical soils, such as alkaline sea muds and mainly calcareous soils of Indonesia and certain very alkaline soils of Bolivia and other localities in South America (Becking, 1961; J. H. Becking, unpublished observations). Clearly, alkaline conditions are favorable for the occurrence of *A. vinelandii* and

probably selective for its distribution. Further, this species may be halophilic to some degree, or at least resistant to salinity, in view of isolation from alkaline sea muds. The presumed halophilic properties need, however, experimental confirmation.

Derx (1951b) designed a method for selective isolation of this species from soil and water sources. The underlying principles of this method were the addition to the enrichment medium of sodium benzoate (1.0%) as an inhibitor in order to suppress the development of *A. chroococcum*, and the use of a special carbon source, such as mannitol or ethanol, which is very readily assimilated by *A. vinelandii*. Derx's method was a further extension of earlier work of Reuszer (1939), who observed that by applying benzoate, benzoic acid, or another phenolic compound to soil, the normal population of *Azotobacter chroococcum* and *A. beijerinckii* was replaced completely by a green-pigment-producing form of *Azotobacter*, which had not been found before in the soil.

Derx's Medium for Selective Enrichment of
Azotobacter vinelandii (Derx, 1951b)

Distilled water	100 ml
Mannitol	0.5 g
or ethanol	1.0 ml
K ₂ HPO ₄	0.5 g
Sodium benzoate	1.0 g
Adjust to pH 7.5–8.0.	

For the isolation of this species from soil, ethanol is preferentially used as carbon source; for its isolation from water samples, the use of mannitol as carbon source is recommended since *Azomonas agilis* (see "Representatives of the Genus *Azomonas*") is usually unable to assimilate this compound. According to the present author, the rather alkaline reaction induced by the addition of sodium benzoate may also be responsible for the selective properties of this medium for the enrichment of *A. vinelandii*.

Numerous strains of *A. vinelandii* were obtained by the present author from Dutch water habitats, such as the Rhine River, and pond and lake water (usually of pH 7.0–7.5) by using Derx's medium with mannitol as carbon source and the supplement of sodium benzoate. In all cases, the enrichment medium was adjusted to pH 8.0–9.0. Use was made of 300-ml Erlenmeyer flasks with 50 ml of medium or 100-ml Erlenmeyer flasks with 20 ml of medium. For the water samples, the sample itself, instead of distilled water, was used as liquid to which the carbon source and salts were added.

V. Jensen (1961) mentioned that L-rhamnose (1.0%) could be used as a carbon source for the selective enrichment of *A. vinelandii*, since only a very small fraction of the strains of the other *Azotobacter* and *Azomonas* species tested could

utilize this compound. When grown in pure culture on L-rhamnose, *A. vinelandii* develops profusely within 3–5 days at 25°C, while the other *Azotobacter* species that can utilize this compound only produce some development after 1–2 weeks. Therefore, in spite of the presence of other *Azotobacter* species, *A. vinelandii* soon becomes dominant in such an enrichment medium.

Using the L-rhamnose enrichment medium, V. Jensen (1961) observed *A. vinelandii* to be sparsely distributed in normal soil. It was only present in a very few garden soils and seemed to be restricted to the most fertile soils. Although Johnstone (1974) reported that *A. chroococcum* and *A. beijerinckii* do not utilize L-rhamnose as sole source of carbon, according to the present author, this is not always true. Utilization of L-rhamnose is not a common feature of strains of these species, when these are obtained as random isolates with the more common sugars, but some strains utilizing this carbon source can be secured in enrichment media by using L-rhamnose as sole source of carbon. Also, Thompson and Skerman (1979) observed that one of the 19 *A. chroococcum* strains tested could utilize L-rhamnose, while Claus and Hempel (1970) isolated both *A. chroococcum* and *A. beijerinckii* from soil and water samples with L-rhamnose as sole substrate.

Claus and Hempel (1970) observed that resorcin, ethylene glycol, or glutarate, all in 0.1 or 0.2% (wt/vol) concentration, are very selective carbon sources for *A. vinelandii*, and that a number of strains could be isolated from soil by using these compounds as sole source of carbon in enrichment media. The above-mentioned carbon compounds apparently cannot be utilized by the more common *Azotobacter* species.

A. vinelandii strains have numerous peritrichous flagella, in general, but Derx (1951b) isolated nonflagellated strains of *A. vinelandii* for which he proposed the name *Azotobacter non-vinelandii*, which name is, however, considered not to be validly published under Rule 23 of the Bacteriological Code (reference is not an exact match year Lapage et al., 1975). Another characteristic of these strains, which distinguishes them from typically flagellated strains of *A. vinelandii*, is the ability to produce a black pigment in the presence of benzoate (Derx, 1951b).

In multiple tests for numerical analysis, Thompson and Skerman (1979) confirmed that all *A. vinelandii* strains tested could readily utilize rhamnose as sole source of carbon, in contrast to most strains of other species. Moreover, they observed that *A. vinelandii* could utilize caproate, caprylate, and meso-inositol, compounds which generally are not utilized by the other *Azotobacter* species. Furthermore, 0.1%

phenol can be used in enrichment cultures to inhibit the growth of other *Azotobacter* species, and incubation at 37°C particularly favors the development of this species. According to these authors, the nonmotile *Azotobacter non-vinelandii* strains may be regarded as a special subgroup that differs from typical *A. vinelandii* strains by the inability to utilize raffinose and by the utilization of pimelate, suberate, and sebacate as sole sources of carbon. In addition, in contrast to typical *A. vinelandii*, these strains were resistant to brilliant green at a concentration of 10 µg/ml.

The presence of *A. vinelandii* in enrichment media can be detected by a color change of the medium, which turns yellow, green, or violet. On nitrogen-free, mineral agar plates, a water-soluble yellow, green, or violet fluorescent pigment is excreted into the medium, but they do not produce any nondiffusible pigment. Pigment production into the substrate is stimulated by low-iron concentration or iron deficiency of the medium (Becking, 1962). As shown by Johnstone (1955, 1957b) and Johnstone and Fishbein (1956), the fluorescence of the pigment under ultraviolet light shifts with pH changes, and different fluorescence curves are obtained with the diffusible pigments of *A. vinelandii* and *Azomonas agilis*. Thus, fluorescence measurements also have diagnostic value in distinguishing between both species.

Azotobacter paspali

Cells are long, bluntly ended rods. Mean cell dimensions are 7.0–10.9 µm long × 1.3–1.7 µm wide; sometimes shorter rods of 3.2–4.2 µm long × 1.6–1.9 µm wide are seen. Cells in young cultures often form long filaments. A yellow-green, fluorescent or red-violet, water-soluble pigment is excreted into the medium.

This species, described by Döbereiner (1966), was originally isolated on Winogradsky's silica-gel plates impregnated with a mineral salt solution (see sieved-soil plate method) with a pH of 6.5 and calcium citrate as sole source of carbon. Later (Döbereiner, 1970), a N-free, mineral sucrose agar (a modification of Lipman's [1903b, 1905] medium) was recommended, because it gave satisfactory results and it was much easier to prepare.

Nitrogen-free, Mineral Sucrose Agar for Isolation of *Azotobacter paspali* (Döbereiner, 1970)

Distilled water	1 liter
K ₂ HPO ₄	0.05 g
KH ₂ PO ₄	0.15 g
MgSO ₄ ·7H ₂ O	0.20 g
CaCl ₂	0.02 g
CaCO ₃	1.0 g
Na ₂ MoO ₄ ·2H ₂ O	0.002 g

FeCl ₃ (10%, aqueous solution)	1 drop
Bromthymol blue (0.5%, ethanol solution)	10 ml
Sucrose	20 g
Agar	20 g

Adjust the pH to ca. 7.0.

Plates with this medium were inoculated with root-surface (so-called rhizoplan) soil of a grass species, *Paspalum notatum*. The soil (about 20–50 mg per plate) was usually scattered directly from the roots on the plates. However, the soil also can first be passed through a sieve (0.5-mm mesh), and then 50 mg can be weighed out and scattered over the plates for quantitative tests. The plates were incubated at 35°C.

Differentiation of *A. paspali* from the other *Azotobacter* species on silica-gel plates with calcium citrate as carbon source is relatively easy. Colonies appear 4–5 days after inoculation and these produce an intense yellow pigment, which diffuses into the silica gel below the colony. The colonies are relatively small and raised and readily solubilize the opaque white calcium citrate layer at the top of the silica gel, giving the appearance of many little holes. Later, the colonies spread rapidly and become flat.

On the above-mentioned agar medium, *A. paspali* colonies appear 2–3 days after inoculation and incubation at 37°C. The colonies are dense, raised, and yellow in color due to acid production, because bromthymol blue is added as an indicator to the medium.

The acid-producing ability of this species is not found in any other *Azotobacter* species. Moreover, the ability of *A. paspali* to use organic compounds (only 17 out of 159 tested by Thompson and Skerman, 1979) is much more limited than that of other *Azotobacter* species. *A. paspali* cells are usually 7–12 µm long and 1.3–1.7 µm wide, but occasionally exceptionally long rods (up to 60 µm × about 2.0 µm) are seen. These are typical for this species and are a significant morphological feature, which is not seen in any other *Azotobacter* species. A further characteristic of this species is that cells of the microcolonies are often dimorphic, some colonies possess cells 7–11 µm long, whereas other colonies have cells 3–4 µm in length (Thompson and Skerman, 1979). Cells of older colonies on nitrogen-free agar may reach a length of 60 µm (see above).

From numerical analysis, Thompson and Skerman (1979), concluded that *A. paspali* is not closely related to other *Azotobacter* species. Moreover, they observed an antagonism toward Gram-positive bacteria in this species. In addition, their very restricted habitat—they occur solely in the plant rhizosphere—is unique among all the other *Azotobacter* species. In view of these differences, these authors proposed a new genus for this species, *Azorhizophilus* (Thompson and Skerman 1981). This opinion is, however, opposed by (De Smedt et al. 1980), who found

that the rRNA cistron of *A. paspali* is almost identical with those of *A. chroococcum*, *A. beijerinckii*, *A. vinelandii*, and *A. nigricans*. Moreover, Tchan et al. 1983, using rocket-line immunoelectrophoresis, showed that *A. paspali* is not immunologically separable from other members of this genus. In view of this, it is not desirable to place *A. paspali* in a separate genus.

Strains of *A. paspali* excrete a diffusible, yellow green, in UV-light fluorescent pigment into the substrate, particularly on iron-deficient media.

The association between *Azotobacter paspali* and the grass, *Paspalum notatum*, is highly species-specific; this association is found only in a few other *Paspalum* species (i.e., *P. plicatulum*, *P. dilatatum*, and *P. virgatum*) of 16 other *Paspalum* species tested for this bacterium (Döbereiner, 1970). It was never found in other Gramineae examined and in some Leguminosae and other dicots tested.

The original isolate came from a broad-leaved and hairy *Paspalum notatum* variety "Batatais" (common Bahia grass) in Brazil, but it was later also found in the same and other *Paspalum* species and varieties in Florida (USA) and Puerto Rico, but not in rhizosphere soil of *Paspalum* from Argentina, Paraguay, and South Africa (Döbereiner, 1970). However, according to the present author, no definite conclusion from its absence in the latter three regions can be made, because only a very restricted number of rhizosphere soil samples (one to five) of these localities have actually been examined.

Representatives of the Genus *Azomonas*

Members of the genus *Azomonas* are primarily aquatic. *Azomonas agilis* and *A. insignis* are obligately aquatic organisms, since so far they have only been isolated from freshwater habitats. The only exception is *A. macrocytogenes*, which has been isolated from soil. The latter species was first isolated and described by H. L. Jensen (1955). For a long time, it was only known from a single strain and two variants derived from it, but according to Thompson and Skerman (1979) a total of 7 strains is now available. However, probably all, except one strain, are derivatives or subcultures of Jensen's original strain!

Azomonas species differ from those of the genus *Azotobacter* by a number of morphological and physiological characteristics. They all possess relatively large cells, which frequently occur singly and which have a special type of flagellation that gives the cells a high motility. Microcysts are never formed. Colonies on agar are generally opaque, glistening, smooth, and without insoluble pigment. On iron-deficient

agar media, a yellow-green diffusible pigment is formed; and in some other media, often more red-violet or purple diffusible pigments are produced. Usually pigment production is very pronounced in liquid media and less pronounced on solid media. In *A. agilis* and *A. macrocytogenes*, the pigments are fluorescent in UV light; *A. insignis* has a nonfluorescent pigment.

Identification of *Azomonas* Species

Apart from cell shape and dimensions, which will be covered later in the descriptions of the separate species, *A. macrocytogenes* can readily be distinguished by the formation of enlarged filamentous cells in media with ethanol, a phenomenon absent in *A. agilis* and *A. insignis*. Moreover, flagellation is peritrichous in *A. agilis*, lophotrichous in *A. insignis*, and usually monotrichous (sometimes, however, two flagella at one pole) in *A. macrocytogenes*. With regard to carbon sources as sole source of carbon. It has been observed that mannitol is utilized by *A. macrocytogenes* and not by *A. agilis* and *A. insignis*, and malonate gives just the reverse outcome, i.e., it is utilized by *A. agilis* and *A. insignis*, but not by *A. macrocytogenes*. Finally, maltose is readily utilized by *A. macrocytogenes*, but not by *A. insignis* and only by a minority of the *A. agilis* strains. All species produce water-diffusible pigments, but in contrast to the pigments of *A. agilis* and *A. macrocytogenes*, the pigment of *A. insignis* does not produce fluorescence in UV light.

Azomonas agilis

This species has large, ovoid, ellipsoidal or coccoid cells, often giving it a protist-like appearance (Fig. 6). Cells are seldom found in pairs. Cells are usually 2.5–6.4 µm long and 2.0–2.8 µm wide; sometimes giant cells up to 10.0–13.5 µm long have been observed (Fig. 6). The cells are motile by means of peritrichous flagella. No microcysts are formed. A nondiffusible pigment is not produced, but a diffusible yellow-green or red-violet pigment, particularly on iron-deficient media. In UV light, the pigment gives a bluish-white fluorescence.

This species was first isolated and described by Beijerinck (1901a, 1901b), who obtained it from Dutch (Delft) canal water. Beijerinck used the following enrichment medium:

Enrichment Medium for *Azomonas agilis*
(Beijerinck, 1901a, 1901b)

Canal water	100 ml
Mannitol	2.0 g
K ₂ HPO ₄	0.02 g

The incubation temperature is 25–30°C.

Fig. 6. *Azomonas agilis*. Cells of two strains demonstrating the large, protist-like appearance of the cells and the sporadic occurrence of aberrantly shaped, pleomorphic cells. Living preparations, phase contrast micrographs. Bar = 10 μ m.

Later, Kluyster and van Reenen (1933) and Kluyster and van den Bout (1936) obtained other strains with the same method. A strain isolated by the latter authors from Delft canal water (ATCC 7494) is now the neotype, because Beijerinck's original strain has been lost. It is remarkable that *A. agilis* in pure culture cannot utilize mannitol, so this carbon source must first be degraded by other microbes before it can become available to *A. agilis*. It is also possible that immediately after isolation, the strains can actually utilize mannitol, but that this ability is later lost during purification and therefore absent in pure cultures. Kluyster and van Reenen (1933) observed that, when cultures were streaked immediately from the enrichment medium on plates containing tap water, 2% mannitol, 0.02% K_2HPO_4 , and 1.5% agar, and incubated at 20°C, *A. agilis* develops in 2–3 days to very small colonies about 1 mm in diameter. Growth on agar plates that contain glucose (2%) instead of mannitol as source of carbon was luxurious and with much slime production, but isolation from these plates was not recommended because many accompanying contaminants may develop in the capsular slime produced.

Derx (1951b) designed specific methods for the enrichment of *Azomonas agilis* by eliminating, so far as possible, the development of the more common *Azotobacter* species and of other *Azomonas* species. The underlying principle of Derx's method is that *Azomonas agilis*, in contrast to the more common *Azotobacter* species, is remarkably tolerant to the presence of 1%

sodium benzoate in the medium, although it cannot utilize this compound as a carbon source. Derx also added a carbon compound readily utilizable by *A. agilis*. Mannitol cannot be used as the carbon source because it is normally not utilized by *A. agilis*, but it is assimilated by *Azotobacter vinelandii*. The latter organism is frequently also present in water samples and, moreover, is resistant to 1% sodium benzoate. Therefore, Derx recommended the use of ethanol as sole source of carbon for the isolation of *Azomonas agilis*. The following enrichment medium gave good results.

Selective Medium for *Azomonas agilis* (Derx, 1951b)

Water sample (canal, river, or lake water)	100 ml
Ethanol	1 ml
K_2HPO_4	0.05 g
Sodium benzoate	1.0 g

The enrichment medium is placed in relatively thin layers in Erlenmeyer flasks to allow good oxygen access, e.g., 10–15 ml of medium in 100-ml flasks, or 50 ml medium in 250-ml flasks.

Following Derx's method, the author was able to isolate a large number of *Azomonas agilis* strains from various water sources. The organism proved to be particularly common in strawboard factory wastewater, as already observed by K. T. Wieringa (personal communication; see also Smit, 1954) and by Johnstone (1957a), and in some heavily polluted waters. In clear and clean water of rivers, lakes, and turbulent or rapidly moving, oxygen-rich, mountain brooks and rivu-

lets, it was rarely present and frequently totally absent. In this habitat, it is entirely replaced by *Azomonas insignis*.

The tolerance of *A. agilis* strains to salt concentration up to 1.0% suggest that they are able to live in contaminated waters where concentrations of organic matter and mineral salts can be relatively high. Also its resistance to iodoacetate (1 μ M) points in this direction, and this compound could be used for the selective enrichment and isolation of this species (Thompson and Skerman, 1979).

In agreement with this general pattern of being able to survive in polluted environment, nitrate is never or rarely reduced to nitrite by strains of *A. agilis* in contrast to strains of *A. insignis*. Growth experiments using *A. agilis* strains on nitrate-containing media incubated in air revealed that nitrate is an inert, nonutilizable compound for them, and thus they are able to fix molecular nitrogen in the presence of nitrate in the medium (Becking, 1962). In 19 out of 20 *A. agilis* strains tested, vanadium was unable to replace molybdenum in nitrogen fixation (Becking, 1962), indicating that they predominantly have only a molybdenum-activated nitrogenase system.

Azomonas insignis

Colonies on nitrogen-free media are usually small, smooth, translucent, and low convex. They show a low proportion of extracellular polysaccharides. Cells are round or ellipsoidal and are usually 2.5–3.9 μ m in length and 1.7–2.6 μ m in width. On average, they measure $3.1 \times 1.9 \mu$ m (Derx, 1951a). The cells have lophotrichous flagella. No microcysts are formed. On iron-deficient media, a yellow-green, red-purple, or violet pigment may be produced. The pigments are, however, not UV fluorescent.

As will be shown in the enrichment methods for this species, ethanol and salts of organic acids are preferential carbon sources for the isolation of *A. insignis*. On the whole, the utilization of organic carbon compounds as sole source of carbon for growth and energy is very restricted in this species (see later). The type strain of Derx (1951a), which is no longer extant, could not utilize glucose as sole source of carbon. It was probably lost by subcultivation on glucose-containing agar slants. New isolates (see V. Jensen, 1955) could utilize glucose, but with regard to carbohydrate utilization, in all strains tested, it is limited to only two, D-glucose and D-fructose (Thompson and Skerman, 1979).

This species was first isolated and described by Derx (1951a). It was obtained from water of clear, rapidly flowing mountain streams and small rivulets of the Cibodas Nature Reserve,

Western Java, Indonesia (ca. 1,400 m altitude). These rather turbulent streams have limpid, oxygen-rich water, which contains much soluble calcium. *Azomonas agilis* could never be isolated from these sources (see above).

Derx (1951a) recommended the following medium for the specific enrichment of *A. insignis* from these water sources:

Selective Medium for *Azomonas insignis* (Derx, 1951a)

Water sample	100 ml
Calcium formate	0.5 g
Ethanol	1.00 ml

The enrichment medium is placed in rather thin layers in Erlenmeyer flasks, i.e., 20–25 ml in 100-ml flasks or 50 ml in 250-ml flasks. Incubation is at 25–30°C. Calcium formate is added to the medium to inhibit the development of various other microbes, including *Azotobacter* species and other *Azomonas* species. *A. insignis* does not utilize calcium formate but is rather resistant to it. Ethanol is added as sole source of carbon because it is a preferential carbon source for *A. insignis*. According to Derx (1951a), his strains of *A. insignis* could not utilize glucose or mannitol. A nonvolatile carbon source, which also gives good growth and can be used for maintenance in pure culture on agar slants is calcium malate or calcium succinate. Therefore, the use of nitrogen-free, mineral agar plates with calcium malate (0.5%) or calcium succinate (0.5%) as sole carbon source can also be recommended for isolation of *A. insignis* from enrichment cultures.

Pure cultures can also be grown in liquid medium: tap water (for trace element supply), to which is added K_2HPO_4 (0.05%) and ethanol (0.5–1.0%, or about 0.5–1.0 ml per 100 ml medium). Growth is obtained in 24 h at 25–30°C. After several days, the medium turns milky white, later blue-gray, and after about a week sometimes to violet (see above).

V. Jensen (1955) isolated six strains of *A. insignis* from surface water of fast-flowing brooklets and streams with very limpid fresh water in Denmark, but occasionally also from stagnant and somewhat polluted water (e.g., his strains 7 and 9). None of his isolates could utilize mannitol but, in contrast to Derx's strains, all the Danish strains could utilize glucose as sole source of carbon. Two of Jensen's strains were also able to grow in a medium that contained sodium benzoate (1.0%).

Enrichment Medium for *Azomonas insignis* (V. Jensen, 1955)

Water sample	25 ml
K_2HPO_4	0.02%
Ethanol	1.0% (or about 0.25 ml)
or	
Water sample	25 ml
K_2HPO_4	0.02%
Ethanol	1.0% (or about 0.25 ml)
Sodium benzoate	1.0%

The water samples are placed in 100-ml Erlenmeyer flasks.

Thompson (see Thompson and Skerman, 1979) isolated *A. insignis* from a rusty-brown, probably iron-oxide-rich water of a slow-flowing Australian creek with a pH of 6.7, using an enrichment medium recommended by V. Jensen (1955), by adding to the water sample 0.02% K_2HPO_4 and 1% ethanol. The strain isolated (WR-51) was very similar to Derx's type strain as this strain also could not utilize glucose and excretes a violet diffusible pigment into the medium. In this respect it can be regarded as a neotype of Derx's original strain.

The acid tolerance of *Azomonas insignis* was also tested by V. Jensen (1955) of the other *Azomonas* and *Azotobacter* species. Most *A. insignis* strains could not grow in a medium with a pH lower than 5.7–5.9, although a few could produce faint growth at pH 5.5. Of the two *Azomonas agilis* strains tested, one could produce faint growth at pH 5.3, and one *Azotobacter beijerinckii* strain could even grow normally at pH 5.2. The one *Azotobacter chroococcum* strain tested in the survey could not grow below pH 6.1.

Other experiments also showed that *Azomonas insignis* strains have, in general, a preference for slightly alkaline conditions for optimal growth and nitrogen fixation. Of nine strains tested, three could grow at pH 6.0, but all strains grew at pH 10.0 (Thompson and Skerman, 1979). With respect to temperature requirements for growth, *A. insignis* strains seems to be able to grow at relatively lower temperature in comparison to other *Azotobacteraceae*. Nine of the 10 *A. insignis* strains tested by Thompson and Skerman (1979) could grow at 9°C, while the maximum growth temperature was 32°C.

A considerable reduction of the capacity to utilize carbon compounds by *A. insignis* compared to other *Azomonas* and *Azotobacter* species was first noted by V. Jensen (1955). Of the 26 compounds studied, *Azotobacter chroococcum* could utilize 16, *Azotobacter beijerinckii* on the average about 14, *Azomonas agilis* 11, and *Azomonas insignis* only 8. In a general survey, Thompson and Skerman (1979) tested 161 organic carbon compounds as sole source of carbon for *A. insignis*. Of these, 21 compounds could be utilized by nearly all *A. insignis* strains, 9 compounds could be utilized by a few strains, and no strain could utilize any of the 131 other organic carbon compounds tested.

Azomonas macrocytogenes

In contrast to the two previous *Azomonas* species, *A. macrocytogenes* is isolated from soil. The species is primarily known from one isolate, called strain O (original), and two variants derived later, strains M (mutant) and I (intermediate). Although Thompson and Skerman (1979)

described seven strains, most of them are subcultures or derivatives of the original strains, and only one, a strain designated as the cotype of *Azotobacter agilis* subsp. *jakutiae* Krasil'nikov (1949), had another origin.

The original strain was isolated by H. L. Jensen (1955) in an attempt to isolate *Beijerinckia* from Danish soil. The isolate appeared on a nitrogen-free, mineral sucrose agar of about pH 5.5, seeded with garden soil (a fertile loam, pH 7.5) of the State Laboratory of Plant Culture, Lyngby, Denmark.

As could be anticipated from its isolation procedure, the type strain (type O and its variants) can produced good growth and nitrogen fixation in a nitrogen-free medium in the pH range of 4.6–6.9; one variant grew also at pH 4.3. This species is therefore even more acid tolerant than Tchan's (1953) and Jensen and Petersen's (1955) strains of *Azotobacter beijerinckii*.

Apart from morphological properties, such as ellipsoidal or rod-shaped cells, usually 2.5–3.5 µm in length and 1.6–2.1 µm wide, occurring singly or in pairs and occasionally forming short chains, and on media containing ethanol, the formation of very large coccoid, spindle-shaped or filamentous (up to 100 µm) cells, also physiological properties are important. The type strain showed no utilization of starch and rhamnose, but mannitol is utilized. Moreover, *A. macrocytogenes* strains can be differentiated from other *Azomonas* species by the utilization of mannitol (negative in *A. agilis* and *A. insignis*) and maltose (not utilized by *A. insignis* and most strains of *A. agilis*), and by its nonutilization of malonate (utilized by both *A. agilis* and *A. insignis*). In addition, *A. macrocytogenes*, being a soil organism, is more resistant to desiccation than *A. agilis* and *A. insignis*, which generally do not survive on silica gel for more than 2 days (Thompson and Skerman, 1979). However, no microcysts are formed, although microcyst-like structures occasionally are produced. These structures are more like capsules lacking the characteristic exine layer of a microcyst. Moreover, the cells sometimes have the tendency to become Gram-variable, i.e., to change from Gram-negative to Gram-positive.

The cells bear monotrichous flagella, but sometimes there are two flagella at one pole. Colonies do not produce a nondiffusible pigment, but on iron-deficient media, yellow-green or red-violet diffusible pigments are produced, which give a blue-white fluorescence in UV light.

In a numerical analysis and in the constructed dendrogram of relationships, Thompson and Skerman (1979) showed that *Azomonas macrocytogenes* fused at a low hierarchical level with *Azotobacter paspali*. At a higher level, the *Azomonas macrocytogenes*—*Azotobacter*

paspali group fused with the two other *Azomonas* species before fusing with *Azotobacter*. This was a motive for these authors to propose a new genus, *Azomonotrichon* (Thompson and Skerman 1979) for *Azotomonas macrocytogenes*. However, (De Smedt et al. 1980) showed that the rRNA cistrons of *Azomonas insignis* and *A. agilis* differ as much from each other as they do from *Azomonas macrocytogenes* and from *Azotobacter*. Therefore, there is no reason to create a new genus for *Azomonas macrocytogenes*, although more genome comparisons of the various members of the Azotobacteraceae would probably be useful in clarifying its exact taxonomic position. It is noteworthy that Rubenchik (1959) transferred *Azomonas macrocytogenes* to the genus *Beijerinckia* as *B. macrocytogenes* because it fixed nitrogen at pH values of 4.5–5.0 and produced acid from certain carbohydrates. In support of this, Thompson and Skerman (1979) noted that *Azomonas macrocytogenes* produces colony-retained homopolysaccharides from sucrose and saccharose, and this is only found in this group and in most strains of the group containing the *Beijerinckia* species.

Preservation of Cultures

For routine maintenance, *Azotobacter* and *Azomonas* cultures should be subcultured at monthly or bimonthly intervals on nitrogen-free mineral agar containing glucose or sucrose (1 or 2%). For those strains which cannot assimilate glucose (e.g., *Azomonas insignis*), another appropriate carbon source (e.g., an organic acid such as calcium malate or calcium succinate) can be chosen.

Poor results were obtained by lyophilization in skim milk or dextran-sodium glutamate solution on filter paper in small glass vials under vacuum with storage of the closed vials at room temperature in the dark. Antheunisse (1972, 1973) compared this method with storage of cultures on the usual agar media in normal culture tubes, plugged with sterile rubber seals, and stored in the dark at room temperature. Tests for viability of the cultures were made after periods of 1 to 10 years. The outcome showed that lyophilization of *Azotobacter* and *Azomonas* gave very poor results. Only 32% of the cultures were viable after 6 years. The rate of survival of *Azotobacter vinelandii* was relatively high, but that of *A. chroococcum* was low and that of *Azomonas agilis* was nil. In contrast, the 65 *Azotobacter* and *Azomonas* strains kept on sealed agar slants for 3–10 years gave an average viability of 60%. In this case, both *Azotobacter vinelandii* and *Azomonas agilis* gave good survival rates (86 and 78%, respectively).

In the author's laboratory, *Azotobacter* and *Azomonas* cultures are usually kept in normal culture tubes (with cotton plugs) under a seal of sterile liquid paraffin or mineral oil at room temperature (sometimes also at 4°C); such cultures generally survive for at least 3–5 years (J. H. Becking, unpublished observations). Care should be taken that the oil completely covers the agar slant, because if the agar medium remains in contact with air, the agar will dry out and the culture may die.

Physiological and Biochemical Aspects

Azotobacteraceae are aerobic, heterotrophic, nitrogen-fixing organisms and therefore possess all oxidative enzymes for the degradation of the numerous organic carbon compounds utilizable by the various species as sole source of carbon and energy. Many of these enzymes are constitutive, but some are induced by the particular carbon substrate involved. Many publications have appeared on these enzymes, including some on the kinetics of their induction, beginning with the Wisconsin school (Stone and Wilson, 1952a, 1952b; Repaske and Wilson, 1953; Repaske, 1954; Williams and Wilson, 1954; Wilson and Wilson, 1955; Shutter and Wilson, 1955; Alexander and Wilson, 1956; Marr and Marcus, 1962), but they will not be discussed here in view of space limitations. Only some characteristic enzymes associated with nitrogen-fixation in Azotobacteraceae and the relation between the oxidative pathway and nitrogen fixation will be discussed.

The oxidative pathway in Azotobacteraceae as source of energy (ATP) follows the TCA cycle. It has been studied in many investigations (see above) using whole-cell suspensions or cell-free extracts to test the various intermediates of the TCA cycle, such as acetate, malate, succinate, α -ketoglutarate, and citrate. Also, the effect of oxygen on nitrogen fixation and the high respiratory activity of Azotobacteraceae have received special attention, since reference is not an exact match Meyerhof and Burk (1928) and Burk (1930), first observed it, and it was the subject of many later studies (Tschapek and Giambiagi, 1955; Parker and Scutt, 1958, 1960; Dilworth and Parker, 1961). All the studies found that high oxygen levels, even atmospheric levels of oxygen, inhibited the nitrogen fixation activity in *Azotobacter*. Moreover, the exceptionally high respiratory quotients of *Azotobacter* species obtained by manometric methods were remarkable; Q_{O_2} values of 20,000 $\mu\text{l O}_2/\text{h}$ or 4,000–5,000 $\mu\text{l O}_2/\text{mg dry wt/h}$ have regularly been

measured (Williams and Wilson, 1954; Shutter and Wilson, 1955). Both observations have led to detailed investigations on the role of oxygen in the nitrogenase complex. Experiments revealed that in *Azotobacter* a special mechanism operates which protects the oxygen-sensitive nitrogenase from oxygen damage. The high respiration rate of Azotobacteraceae was explained as a mechanism which scavenges oxygen from the dinitrogen-fixing site of nitrogenase (Dalton and Postgate, 1969a). This process, called the “respiratory protection” of nitrogenase, is coupled with a multitude of cytochromes and redox proteins (Haddock and Jones, 1977), thus maintaining the nitrogenase in an essentially anoxic environment inside cells that nevertheless derive energy from aerobic metabolism.

The significance of respiratory protection has been argued, and alternative mechanisms have been suggested. A prominent argument was that the nitrogenase complex, which consists of two components (see later), was extremely sensitive to oxygen, being rapidly and irreversibly inactivated upon exposure to air, but nitrogenase in cell-free extracts of *Azotobacter* is relatively oxygen stable (Bulen et al., 1964; Kelly, 1969). The Brighton, England nitrogen-fixation school also suggested that if O₂ enters the cell more rapidly than it can be removed by respiration (i.e., by “respiratory protection”), an alternative control mechanism operates for which they proposed the name “conformational state protection,” i.e., a protection by some steric arrangement of the components (Dalton and Postgate, 1969a). In the latter mechanism, during O₂ stress, nitrogenase binds to a 2Fe-2S protective protein, also called Fe/S II, to give an O₂-stable complex that is protected from O₂ damage, but that is inert to nitrogenase substrates. When the oxygen stress is low or lowered by excessive respiration, the protected complex dissociates to give active nitrogenase. Such protective proteins have been isolated and characterized for *A. chroococcum* (Robson, 1979) and for *A. vinelandii* (Scherings et al., 1983).

However, some alternative mechanisms have been proposed. Oppenheim et al. (1970a, 1970b) suggested that protection against oxygen was due to a major cytoplasmic membrane component that appears in these organisms when grown in nitrogen-free medium, while Yates (1970) suggested a form of respiratory control by nucleotides (ATP) operating in *Azotobacter*. Also, Kuhla and Oelze (1989) found a dependence of nitrogenase switch-off upon oxygen stress on the nitrogenase activity in *Azotobacter vinelandii*. Their results suggested that the flux of electrons to the nitrogenase complex, rather than cellular oxygen consumption (qO₂), stabilizes nitrogenase activity

against O₂ inactivation in aerobically growing *A. vinelandii*.

From the observations mentioned above, it may be concluded that the mechanism of O₂ control and the absence of a serious inhibition of functioning nitrogenase by O₂ is a rather complex process, which may involve several different systems.

Although nitrogenase is the most important enzyme for aerobic nitrogen-fixing bacteria like the Azotobacteraceae, this enzyme is also found in a great number of other microorganisms belonging to quite-different taxonomic groups and affiliations. The main properties of nitrogenase (i.e., of the main species of nitrogenase, see later) can be summarized as follows: it consists of two proteins; it is sensitive to oxygen or it can be destroyed by oxygen; it contains the transition metals Fe and Mo; it needs Mg²⁺ ions to be active; it converts ATP to ADP when functioning; it is inhibited by ADP; it reduces nitrogen and several other small triply bonded molecules (such as C₂H₂ and CN); and it reduces H⁺ ions to gaseous H₂ even when N₂ is present. The two proteins forming this nitrogenase are a large one (MW of about 220,000) and a smaller one (MW of about 60,000). Both proteins contain Fe (amounts variable), and this metal is essentially accompanied by S atoms. The large protein contains in addition two atoms of Mo and is therefore usually called the molybdoprotein. The proteins of the nitrogenase complex are often also called component I and component II. Furthermore, it is interesting that the two proteins are very similar in different nitrogen-fixing organisms. Their similarity is so great that it is possible to interchange these proteins with the proteins of other nitrogen-fixing microbes, regardless of their origin (e.g., *Klebsiella pneumoniae*, *Bacillus polymyxa*, and *Clostridium pasteurianum*) yielding fully active preparations (Bulen et al., 1966; Detroy et al., 1968; Dahlen et al., 1969).

Nitrogenase reduces N₂ to NH₃ and, for this function, it needs adenosine triphosphate (ATP). In vitro, 16 ATP molecules are consumed to convert one N₂ to two NH₃ molecules, and eight electrons are also involved:

Actually, the reduction of N₂ to two NH₃ requires six electrons, equivalent to 12 ATP molecules. It has been shown that two electrons or four ATPs are used for the formation of one molecule of H₂. In growth experiments with *Azotobacter chroococcum* in continuous culture, Dalton and Postgate (1969b) demonstrated that nitrogen fixation entrained a maintenance coefficient of 1.06 g substrate/g organism/h compared with about

0.40 for ammonia assimilation. Assuming that most of this maintenance was directed to respiratory protection of nitrogenase, an extrapolated maximum requirement of 4 moles ATP/mole N_2 fixed was observed.

In other growth experiments, Dalton and Postgate (1969a) observed that, at 0.03 atm O_2 , nitrogen-limited, continuous cultures of *A. chroococcum* fixed about twice as much N_2 /g carbon source utilized than at atmospheric pressure (i.e., 0.20 atm O_2), confirming earlier growth experiments by other authors (Becking, 1971). The specific effects of different O_2 levels on nitrogen-fixation efficiency of *Azotobacter* have already been discussed (see "General Identification").

As noted before, the nitrogenase system in *Azotobacter* consists of two nonheme iron proteins, i.e., a MoFe protein called Component I, which has been crystallized (Burns et al., 1970; Shah and Brill, 1973) and was shown to be a tetramer of 245,000 daltons (Swisher et al., 1977; Shah and Brill, 1977) containing two Mo atoms per molecule, and a protein called Component II, which is a Fe protein, a dimer of two identical subunits of 31,200 daltons, containing 289 amino acids (Hausinger and Howard, 1980). Thus, apart from Fe, the uptake of Mo by the organism is essential and a prerequisite for active functioning of the nitrogenase complex. Particularly, Mo deficiency or Mo depletion of the medium of Azotobacteraceae cultures limit their growth under nitrogen-fixing conditions. In growth experiments, it was shown by Becking (1962) that the Mo requirements of various *Azotobacter* and *Azomonas* species differ. Half-maximal nitrogen fixation was obtained in *A. chroococcum* at about 0.05 ppm Mo and in *A. vinelandii* at 0.0004 ppm Mo, whereas the same half-maximal growth value is reached in *Azomonas agilis* at 0.0002 ppm Mo. In these growth experiments, Becking (1962) further observed that in the majority of *Azotobacter chroococcum* and *A. vinelandii* strains, vanadium could replace molybdenum under nitrogen-fixing conditions. Of the 10 *A. chroococcum* strains tested, only three were unable to utilize vanadium as a substitute for molybdenum in nitrogenase and, in 19 out of the 20 *A. vinelandii* strains tested, vanadium was able to replace molybdenum in the nitrogen-fixation process. However, in all except one of 20 *Azomonas agilis* strains simultaneously tested, vanadium was unable to replace molybdenum in nitrogen fixation. Moreover, nitrogen fixation with vanadium was reduced to two-thirds of that produced by molybdenum. Experiments also demonstrated that for nitrate assimilation, molybdenum was also required in those species, which could assimilate nitrate (most *Azomonas agilis* strains are unable to utilize nitrate). But in

the nitrate reductase system, molybdenum could not be replaced by vanadium. Finally for ammonium assimilation, neither of the two metals is required (Becking, 1962).

In this context, it is of interest that an alternative nitrogenase system lacking molybdenum has been discovered and its existence proved biochemically and genetically. First evidence of such an alternative nitrogen-fixing system came from the genetic studies of Bishop et al. (1980, 1982), who obtained Nif^+ pseudorevertants of the Nif^- strains UW6 and UW10 (see Shah et al., 1973) of *A. vinelandii*. These pseudorevertants displayed growth on nitrogen-free medium at a lower growth rate than the wild type and fixed nitrogen at a rate of 3–4% of the Nif^+ control. Moreover, phenotypic reversion of Nif^- mutants to Nif^+ occurred when they were grown on media lacking molybdenum but containing tungsten, vanadium, or rhenium salts (Bishop et al., 1980, 1982). Under these conditions, there was nitrogen fixation at a low rate although the cells lacked the typical EPR signal of the MoFe protein. These observations led Bishop et al. (1980, 1982, 1986) to propose an alternative pathway for nitrogen fixation in *A. vinelandii*, whose functioning was independent of molybdenum.

Following this, Eady et al. 1987 and Dilworth et al. 1988 demonstrated the existence of a vanadium nitrogenase in *A. chroococcum*. Miller and Eady (1988) showed that, for both the Mo and V nitrogenases present in *A. chroococcum*, low temperature favors the nitrogen reduction by the V nitrogenase. The vanadium nitrogenase of *A. chroococcum* was purified and the properties of the VFe protein were studied (Eady et al., 1987). These authors demonstrated that the VFe protein of the vanadium nitrogenase contained an iron-vanadium cofactor forming the substrate-reducing site (Smith et al., 1988). Also, the Fe protein of the vanadium nitrogenase was purified and characterized (Eady et al., 1988). Raina et al. 1988 characterized the gene for the iron-protein of the vanadium-dependent alternative nitrogenase of *A. vinelandii* and constructed a Tn5 mutant. Finally, the structural genes for the vanadium nitrogenase from *A. chroococcum* have been cloned and the nucleotides have been sequenced (Robson et al., 1989). There is also genetic evidence obtained using deletion mutant analysis that shows that at least in *Azotobacter vinelandii*, there is also a third nitrogenase that lacks both Mo and V (Pau et al., 1989). This has been independently verified, and the existence of an FeFe protein has been demonstrated (Smith, 1989; B.E. Smith, personal communication). Thus, in conclusion, three distinct nitrogenases are now known, each with its own, genetically distinct, Fe protein which acts as an electron transfer agent to either a MoFe, VFe, or FeFe

protein in an ATP-hydrolyzing reaction. The MoFe and VFe proteins have been shown to contain cofactors (FeMoco and FeVco) that form the substrate-reducing sites.

Besides oxygen, hydrogen has also been intensively studied in relation to nitrogenase (Robson and Postgate, 1980). Hydrogen evolution has received attention in the context of the efficiency of the nitrogen-fixing system (Schubert and Evans, 1976; Schubert et al., 1977). It was suggested that in a fully efficient system, all electrons would be used for ammonia production and no hydrogen would be evolved. All Azotobacteraceae have very powerful hydrogenases and therefore, in these organisms, the role of hydrogen in nitrogen fixation was of particular interest. Hydrogen-dependent mixotrophic growth of *A. vinelandii* has been observed (Wong and Maier, 1985). Moreover, hydrogen-mediated enhancement of hydrogenase expression (Prosser et al., 1988) and hydrogen-mediated mannose uptake (Maier and Prosser, 1988) have both been reported for *A. vinelandii*. Recently, competition studies in continuous culture between a Hup⁻ (= Hydrogen-uptake⁻) mutant of *A. chroococcum* and its presumed isogenic Hup⁺ recombinant showed that Hup activity benefitted the organism under nitrogen-fixing and sucrose- or phosphate-limiting conditions, but it was ineffective or disadvantageous under O₂, sulfate, or iron limitation (Yates and Campbell, 1989). The physiological aspects as well as the genetics of the hydrogen-uptake hydrogenase has been lately reviewed by Yates (1988) and Yates et al. 1988.

With regard to the assimilation of combined nitrogen such as ammonia, the usual enzymes, including glutamate dehydrogenase (GDH), glutamine synthetase (GS), and glutamate synthase (GOGAT), have been reported for *A. chroococcum* (Drozd et al., 1972), and some have also been demonstrated in other *Azotobacter* species. GOGAT was found in both soluble and membrane-bound forms in *A. vinelandii*. Assimilatory nitrate and nitrite reductases have been characterized for *A. chroococcum* and *A. vinelandii* (Guerrero et al., 1973; Spencer et al., 1957; Taniguchi and Ohmachi, 1960; Vega et al., 1973).

Genetic Aspects

The first metabolic mutants of *Azotobacter* were described for *Azotobacter vinelandii* by Karlsson and Barker (1948), and shortly afterwards mutants of the same species which do not fix nitrogen were reported by Wyss and Wyss (1950). The first DNA-mediated transformation

in *Azotobacter* was observed by Sen and Sen (1965), who described an interspecific transformation of pigment production between *A. chroococcum* and *A. vinelandii*. Transformation of Nif⁻ strains of *A. vinelandii* with *Rhizobium* DNA have also been described (Page, 1977), together with some other intergeneric transformations between *Rhizobium* and *Azotobacter* (Sen et al., 1969; Bishop et al., 1977a; Maier et al., 1978). Although phages (azotophages) of *Azotobacter vinelandii* and *A. chroococcum* have been isolated (Monsour et al., 1955; Chumil et al., 1980), these phages had limited host ranges and apparently had no transducing ability (Bishop et al., 1977b). An earlier positive report (Wyss and Nimeck, 1962) mentioning interspecific transduction in *Azotobacter* could not be confirmed.

Most studies on mutants of *Azotobacter* have involved the *nif* genes. The first stable *nif*⁻ mutants of *Azotobacter* were described for *A. vinelandii* by Fisher and Brill (1969). These mutants were biochemically analyzed by these authors for the activity of the two nitrogenase components (Shah et al., 1973; Bishop and Brill, 1977).

Regulatory mutants of *Azotobacter* that fix nitrogen in the presence of ammonium have also been isolated and described by Sorger (1968), Gordon and Brill (1972), Bishop and Brill (1977), and Terzaghi (1980b). Such mutants were found particularly among strains resistant to methylalanine. Ammonia-exporting mutants may be important in industry for ammonia production (see "Applications").

Bishop et al. 1980 obtained *nif*⁺ pseudorevertants of some particular *nif*⁻ mutants (UW 6 and UW 10), which could fix nitrogen at a rate of 2–4% of the *nif*⁺ control. From these observations, they inferred the existence of an alternative pathway for nitrogen fixation functioning independently of Mo (see "Physiological and Biochemical Aspects"). Moreover, drug-resistant mutants (Page and Sadoff, 1976; Bishop and Brill, 1977) and amino acid and vitamin autotrophs (Leach and Battikhi, 1978) of *A. vinelandii* have regularly been obtained by mutagenesis and the application of selective media.

On the whole, *Azotobacter* species and, in particular, *Azomonas* species seem to be difficult to mutate or the selection procedures used so far have been inadequate. Sadoff et al. 1979 argued that *A. vinelandii* contains 40 chromosomes per cell, and therefore failure to isolate mutants could result from difficulties in segregation rather than mutagenesis. In view of these difficulties, most information on the *nif* genes comes from *Klebsiella pneumoniae*. It has a good transduction system and a plasmid (pRD1) that carries the entire *nif* cluster of *K. pneumoniae*. The plasmid has been isolated and this system was

most useful in the development of the *Azotobacter nif* genetics, e.g., by the expression of *Klebsiella nif* genes in *Azotobacter* (Cannon and Postgate, 1976).

At the moment, the homology of *nif* genes of *Azotobacter* and other bacteria species is well established, and the genes encoding the two nitrogenase systems in two species (*A. vinelandii* and *A. chroococcum*) have been identified.

A group of genes spanning 25–30 kb of DNA was characterized in *A. chroococcum* after being cloned and their expression studied in *Klebsiella pneumoniae* (Jones et al., 1984). Hybridization to *nif* gene probes from *K. pneumoniae*, coupled with DNA sequencing and complementation analysis, revealed that the *nif* genes *FMV-SUNEKDH* are present in this region (Evans et al., 1985). The genes best characterized for structure and function in *A. vinelandii* and *A. chroococcum* are *nifKDH*. A restriction map for a region of the *A. chroococcum* genome carrying *nif* genes (Jones et al., 1984) confirms close linkage and expression of *nifKDH* as a single transcript, and places *nifV* 15 kb away from *nifKDH*.

The promoters of *nif* genes were observed to share common nucleotide sequences in two regions upstream from the site at which transcription begins in a number of different organisms such as *Azotobacter*, *Klebsiella*, *Rhizobium*, *Thiobacillus*, and *Desulfovibrio*. The structural genes, including that of the VFe protein of the vanadium nitrogenase from *A. chroococcum* (Robson et al., 1989), have been cloned, and nucleotide sequences were determined as already reported. Activator proteins are needed for *nif* gene expression, and genes encoding activator genes have diverged to control expression of the three different enzyme systems responsible for nitrogen fixation. Regulation of *nif* genes in *Azotobacter* is therefore rather complicated.

Similarity of *nif* regulation among *K. pneumoniae* and *A. vinelandii* and *A. chroococcum* has been demonstrated (Kennedy and Robson, 1983). Introduction of the *nifA* gene from *K. pneumoniae* into *Azotobacter* mutants deficient in both components I and II restored the Nif⁺ phenotype to the presumed regulatory mutants but not to a nitrogenase-structural-gene mutant. The results are interpreted to suggest that *nifA* activation of *nif* genes might also be conserved among diazotrophs. Two nitrogen fixation regulatory regions, *nifA* and *nfrX*, in *Azotobacter vinelandii* and *A. chroococcum* have also been identified and characterized (Santero et al., 1988). These investigations are too numerous to cite here fully, but most of them are cited in recent reviews on the genetics of *Azotobacter* and related organisms by Elmerich (1984), Kennedy and Toukdarian (1987), and Kennedy (1989).

Applications

Associative growth of one *Azotobacter* species, *A. paspali*, has been reported to produce growth responses, apparently giving an increase in nitrogen, in forage grasses (Döbereiner, 1970; Döbereiner and Day, 1976).

However, *Azotobacter* inoculants (mainly *A. chroococcum*) also may produce crop responses. Especially in the USSR in the years 1958–1960, numerous field experiments were conducted with *Azotobacter* inoculants (named “Azotobacterin” or “Nitragin”) with agricultural crops like spring wheat, winter wheat, barley, oats, and maize. Mishustin and Shilnikova (1969, 1971) have summarized these results, showing that in some trials, significant yield increases were obtained with a beneficial effect varying from 7–12%. Later, however, this practice was no longer recommended and it has now been abandoned.

However, some workers still claim that *Azotobacter* has a positive effect on crops, e.g., *Azotobacter* inoculation of seeds or seedlings of wheat, rice, onion, tomato, brinjal (*Solanum aestivum*), and cabbage. Significant responses with increases that average 10–20% are reported for such crops (Sundara Rao et al., 1963; Lehri and Mehrotra, 1968, 1972; Mehrotra and Lehri, 1971; Joi and Shinde, 1976; Shende et al., 1977).

Some other workers (Vančura and Macura, 1959, 1961; Brown et al., 1962, 1964) performed field and pot experiments in which artificial inoculation produces increases in the yield of crops. They attributed the beneficial responses in addition to fixed nitrogen made available to the plants by the production of phytohormones such as gibberellins, auxins, and some phenolic compounds (Jackson et al., 1964; Hennequin and Blachère, 1966), giving the plants a better health condition. Also, the production of antifungal antibiotics by *Azotobacter* may play a rôle in these yield increases (Mishustin and Shilnikova, 1969, 1971; reference is not an exact match Laksmi Kumari et al., 1975).

For instance, Meshram and Jager (1983) mentioned an antagonism of isolates of *Azotobacter chroococcum* to *Rhizoctonia solani* on agar plates and *Azotobacter* isolates were tested for their ability to control *R. solani* infection of potato sprouts in sterilized and unsterilized soil. The degree of antagonism exhibited varied strongly among the isolates and was found to be temperature-dependent. Following this, Azad and Aslam (1985) observed that *Azotobacter chroococcum* inoculation increased the yield and the protein content of potato (*Solanum tuberosum*) tubers. Analyses showed that the inoculum increased substantially the population of *A. chroococcum* present in the rhizosphere soil in these experiments.

Bagyaraj and Menge (1978) showed that larger populations of bacteria and actinomycetes were recovered from the rhizospheres of tomato (*Lycopersicon esculentum*) plants inoculated with the mycorrhizal fungus *Glomus fasciculatus* and *Azotobacter chroococcum*, either individually or together, than from those of non-inoculated plants. The dry weights of the tomato plants inoculated with both *G. fasciculatus* and *A. chroococcum* were significantly (62%) greater than non-inoculated plants. These results suggest a synergistic or additive interaction between *Glomus fasciculatus* and *Azotobacter chroococcum*.

Although the practice of using *Azotobacter* inoculants was often unsatisfactory and has been abandoned in many countries, in India a constant stream of publications continues to appear on the beneficial effects of *Azotobacter* on various crops such as sorghum, pearl millet, maize, rice, sesame, wheat, and barley (Ghonsikar et al., 1986; Prasad, 1986; Konde and Shinde, 1986; Shende et al., 1986; Subbian and Chamy, 1984; Rai and Gaur, 1988; Kavimandan et al., 1978; Tiwari et al., 1989). In India, it is also suggested that *Azotobacter* inoculation gives positive growth responses in oak seedlings used in forestry (Pandey et al., 1986).

Outside India, there are now only sporadic reports on the beneficial effects of *Azotobacter* inoculations, and these refer mainly to subtropical regions. Some Egyptian authors have obtained positive results on the growth of the castor oil plant, *Ricinus communis* (Monib et al., 1984), or of wheat (Emam et al., 1986) with *Azotobacter* inoculation.

Monib et al. 1979 also studied the effect of bacterization of barley (*Hordium vulgare*) grains with a selected strain of *Azotobacter chroococcum*. In N-deficient sand, seed inoculation increased plant length, dry weight, nitrogen content in addition to a significant increase in soil nitrogen. In the presence of a mixed soil microflora the beneficial effect of bacterization was less than in monobacterial cultures. *Azotobacter* naturally present in soil also colonized in heavy densities the rhizosphere (rhizosphere) of the barley plants, but their effect on plant growth and soil nitrogen were less as compared with that of bacterization.

In Spain, the beneficial effects of *Azotobacter chroococcum* on root colonization and grain production of maize have been reported (Martinez-Toledo et al., 1988a, 1988b), and in *Sorghum bicolor*, a specific root association with *A. chroococcum* was demonstrated, but there was no interaction influencing the nitrogenase activity in the rhizosphere, probably due to the lack of excretion of a carbon and energy source by the plant (De La Rubia et al., 1989). In addition, in

Israel, positive responses of *Azotobacter* inoculation on the growth of *Setaria italica* have been reported (Yahalom et al., 1984). In Pakistan, Hussain et al. 1985 studied in field experiments the seed inoculation of wheat (*Triticum aestivum*) on the yield in relation to the application of farm yard manure and some N-P-K levels, in which N was given in the form of urea. The results indicated that *Azotobacter* inoculation was more effective as regards to grain yield in the trials where no nitrogen was added, next was farm yard manure and the lowest response was with urea application.

From all these investigations it is clear that, with regard to beneficial effects, the supply of fixed N might not be the sole factor involved or it is only a minor factor and that growth-promoting substances may be involved. In particular, it appears that plant root colonization by bacteria is favorable, probably due to biological control of plant diseases (see e.g., Kloepper et al., 1989).

Some *Azotobacter* mutants may be important for biotechnology and industrial application. Mutants of *A. vinelandii* have been obtained that fix molecular nitrogen in the presence of excess NH_4^+ excretion into the medium (Gordon and Brill, 1972; Shaw et al., 1973). Terzaghi (1980a, 1980b) tried to produce such mutants in a variety of *Azotobacter*/*Azomonas* species, i.e., mutants which could excrete excess ammonia in addition to being able to reduce N_2 in the presence of excess NH_4^+ . She isolated nitrogenase-derepressed (Nif-Drd) mutants of *Azotobacter* in the two *Azotobacter* species (*A. vinelandii* and *A. beijerinckii*) and the two *Azomonas* species (*A. agilis* and *A. macrocytogenes*) tested. Such mutants could only be obtained in *Azotobacter vinelandii* and to a much lesser degree in one strain of *Azomonas agilis*. These mutants, having up to 100% nitrogenase activity and excreting NH_4^+ into the medium without inhibiting the nitrogenase activity, are of industrial significance, for instance by immobilization in Alginate beads, because they offer the opportunity to produce ammonia (which can be used as plant fertilizer) using *Azotobacter* in a biotechnological process.

The Genera *Beggiatoa* and *Thioploca*

ANDREAS TESKE AND DOUGLAS C. NELSON

Introduction

Filamentous sulfur-oxidizing bacteria of the genera *Beggiatoa* and *Thioploca* are some of the largest and most conspicuous bacteria in nature (Schulz and Jørgensen, 2001). Their white or yellow color, their filamentous morphology, the large width and length of their filaments, and their growth pattern in flocs and mats on sediment surfaces makes them highly conspicuous even to the unaided eye. The two genera are distinguished by a single morphological character: *Thioploca* filaments occur in bundles surrounded by a common sheath, whereas *Beggiatoa* filaments do not form this structure and occur as individual filaments. All *Beggiatoa* and *Thioploca* strains have the ability to oxidize sulfide to elemental sulfur that is stored as intracellular sulfur globules, which make the cells highly refractory and conspicuous under the microscope. This characteristic, together with the absence of photosynthetic pigments, has distinguished the genera *Beggiatoa* and *Thioploca* as filamentous members of the “colorless sulfur bacteria” from other filamentous bacteria, for example the cyanobacteria or nonsulfur-oxidizing heterotrophs such as *Cytophaga* and *Flexibacter*. Contrary to earlier assumptions (Reichenbach and Dworkin, 1981), there is no close evolutionary relationship between other gliding filamentous bacteria, and *Beggiatoa* and *Thioploca*.

The metabolic spectrum in *Beggiatoa* ranges from obligate autotrophy with sulfide and other reduced sulfur compounds as energy source, so far found in marine strains only (Nelson and Jannasch, 1983), to seemingly strict heterotrophy based on organic carbon and energy sources (Nelson and Castenholz, 1981a). The *Thioploca* spp. that have been characterized so far, have autotrophic potential (Otte et al., 1999). Biogenic or geothermal sulfide is oxidized to elemental sulfur, and subsequently in autotrophic strains to sulfate, to provide energy and reducing power for CO₂ fixation and biomass synthesis. The electron acceptor for of sulfide oxidation is oxygen (Nelson et al., 1986b) or in some cases

nitrate (McHatton et al., 1996; Otte et al., 1999). The requirement for oxygen and sulfide, two mutually highly reactive chemical species, forces *Beggiatoa* and *Thioploca* into a specialized niche at naturally occurring oxic/anoxic interfaces where these bacteria compete efficiently with chemical sulfide oxidation (Jørgensen, 1982). *Beggiatoa* grows at oxic/anoxic interfaces, where sulfide as electron donor and oxygen as electron acceptor are present simultaneously (Nelson et al., 1986b). Large marine *Beggiatoa* also adapt to fluctuating gradients by increased intracellular storage capacity for oxidants (McHatton et al., 1996). *Thioploca* filaments can bridge spatially separated pools of oxidant and reductant by moving up and down and adjusting their position in a sediment-embedded sheath (Hüttel et al., 1996). *Beggiatoa* and *Thioploca* are effective mat-forming microorganisms; their mats may be less than a millimeter thin (Nelson et al., 1986a) or several centimeters thick (Jannasch et al., 1989b), depending on the dynamics and stability of the sulfide/oxidant interface. The most extensive microbial mats on earth are formed by *Thioploca* on the Chilean and Peruvian continental shelf (Gallardo, 1977) and are of considerable importance as a link of the marine carbon, sulfur and nitrogen cycles (Fossing et al., 1995; Jørgensen and Gallardo, 1999).

The filamentous sulfur-oxidizing bacteria play a special role in the history of microbiology. The concept of chemolithoautotrophy, light-independent biomass production by CO₂ fixation and oxidation of inorganic electron donors, originated with Winogradsky's studies of *Beggiatoa* enrichment cultures (Winogradsky, 1887). Winogradsky described lithotrophy but not autotrophy in this pioneering work, and a full understanding of the concept we now call lithoautotrophy arose from his later pure culture studies of nitrifying bacteria (Brock and Schlegel, 1989). After a protracted search for *Beggiatoa* strains that could grow autotrophically on reduced sulfur compounds and CO₂ without any addition of organic substrates (briefly outlined in Nelson and Castenholz, 1981b), autotrophic marine *Beggiatoa* were isolated in pure culture

and characterized in detail a century after Winogradsky's pioneering work (Nelson and Jannasch, 1983; Hagen and Nelson, 1996). In nature, the autotrophic biomass production of *Beggiatoa* mats and other sulfur-oxidizing bacteria represents "primary production" if the source of sulfide is geothermal, or "secondary production" if it recaptures some of the energy of anaerobic carbon remineralization via sulfate reduction that produces sulfide (Jannasch, 1989a).

Habitats

The filamentous sulfur oxidizers *Beggiatoa* and *Thioploca* grow at oxic/anoxic interfaces on freshwater, brackish and marine sediments where sulfide of biological or geothermal origin comes in contact with oxygen or nitrate in the overlying water column. *Beggiatoa* species rely on the simultaneous presence of sulfide and oxidant in steep, narrowly overlapping, opposing gradients (Jørgensen and Revsbech, 1983a; Nelson et al., 1986b) or are adapted to alternating exposure to sulfide and oxidant in frequently fluctuating water flow (Gundersen et al., 1992). *Thioploca* filaments have the ability to adjust their position in redox gradients by emerging from, retreating into, and moving up and down within their sediment-embedded sheaths (Hüttel et al., 1996). This ecophysiological flexibility allows *Beggiatoa* and *Thioploca* to colonize a wide spectrum of freshwater and marine environments. Typical freshwater *Beggiatoa* habitats are sulfur springs (Uphof, 1927; Caldwell et al., 1975; Nelson and Castenholz, 1981a; Fukui et al., 1999), ditches, puddles, wetlands, and lake sediments (Scotten and Stokes, 1962; Pringsheim, 1964; Strohl and Larkin, 1978; Fig. 1). In rice paddies that experience sulfate-enrichment, *Beggiatoa* grows in association with rice roots (Pitts et al., 1972; Joshi and Hollis, 1977). In the marine

environment, *Beggiatoa* can be found in a wide range of habitats, including organic-rich, coastal marine sediments (Jørgensen, 1977; Mussmann et al., 2003), salt marshes (Nelson et al., 1982b; Fig. 2), naturally eutrophic, oxygen-depleted bays (Graco et al., 2001), oxygen-depleted marine basins (Williams and Reimers, 1983; Kuever et al. 1996), geothermally active submarine caves (Mattison et al., 1998), hydrothermal vents (Jannasch et al., 1989b; Nelson et al., 1989c; Fig. 3), cold sulfide seeps (Sassen et al., 1993), hydrocarbon seeps (Larkin et al., 1994), and sulfidic sediments overlying gas hydrates (Sahling et al. 2002). Highly localized areas of anaerobic decomposition, such as a whale carcass on the ocean floor, also lead to enrichment of *Beggiatoa* spp. (Smith et al., 1989).

In general, *Beggiatoa* spp. prefer a microoxic habitat at the interface of a source of reduced sulfur, typically sulfide, and oxygen or nitrate as electron acceptors. Detailed microelectrode surveys with non-vacuolate *Beggiatoa* species in gradient cultures showed that oxygen-respiring

Beggiatoa grows at oxygen partial pressures of <6% air saturation (Nelson et al., 1986a; Nelson et al., 1986b). Similarly, low oxygen partial pressures have been found in *Beggiatoa* mats in nature, on organic-rich marine sediments (Fenchel and Bernard, 1995). In photosynthetic cyanobacterial mats, *Beggiatoa* filaments constitute a part of the mat matrix and follow the diurnally changing sulfide-oxygen interface (Garcia-Pichel et al., 1994). Large marine *Beggiatoa*, which most likely depend on nitrate as electron acceptor (McHatton et al., 1996), are found growing in dense mats at nitrate-rich, oxygen-poor sediment-water interfaces. These large *Beggiatoa* reach filament diameters of up to 200 μm and grow in patchy mats on the surface of hydrothermal vent sediments and of cold-seeps; they are among the largest known prokaryotes (Larkin and Henk, 1996). Interestingly, large *Beggiatoa* spp. growing in land-locked saline springs often resemble their counterparts in the marine environment and share the conspicuous vacuolated phenotype that is typical of many marine populations (Kolkwitz, 1918).

Thioploca forms ensheathed bundles of filaments that can extend and retreat into the sediment, several cm in large marine species, although the bulk of the biomass is still found near the sediment surface (Schulz et al., 1996; Schulz et al., 2000). With the discovery of extensive marine mats of large *Thioploca*, this bacterium emerged as a significant microbial component of the sulfur and nitrogen cycles in the oceans (Fossing et al., 1995). Extensive mats of large *Thioploca* were found on the Chilean and Peruvian continental shelf, where they grow on sediments that underlie the deoxygenated water masses of the Peru-Chile countercurrent (Gallardo, 1963; Gallardo, 1977). Bundles of a few or up to one hundred *Thioploca* filaments are surrounded by a polysaccharide sheath (Fig. 4). A mesh of these conspicuous, ensheathed whitish bundles, each up to several centimeters long and one millimeter thick, is embedded in soft, organic-rich sediments and forms a mat of several cm thickness (Fig. 5). In its entirety, this *Thioploca* habitat stretches—with considerable patchiness and seasonal variability—from the continental shelf of south-central Chile to Peru (Gallardo, 1975; Rosenberg et al., 1983; Zafra et al., 1988; Gallardo et al., 1995; Carrasco et al., 1999), over a distance of 3000 km, and constitutes the most extensive microbial mat habitat on Earth (Jørgensen and Gallardo, 1999). *Thioploca* has been found in coastal regions with similar upwelling regimes, where high organic productivity causes significant oxygen depletion at the bottom waters that overlay organic-rich sediments with high sulfate reduction rates. Examples include the coast of

Fig. 4. Rinsed *Thioploca* bundles from the Chilean Coast. The gelatinous, transparent sheaths harbor white *Thioploca* filaments. The larger filaments of the species *Thioploca araucae* have a diameter of ca. 40 μm . Courtesy of Markus Hüttel.

Fig. 5. Gravity core with sediments harboring *Thioploca* mat, from the Chilean Pacific shelf near Concepción. Individual white *Thioploca* filaments extend several cm into the dark brown sediment. Most of the *Thioploca* biomass is found near the sediment surface where *Thioploca* filaments form a dense web. Courtesy of Markus Hüttel.

Oman (Schmaljohann et al., 2001), and the Benguela current ecosystem off Namibia (Gallardo et al., 1998). Early studies of *Thioploca* were based on freshwater and brackish water habitats, for example in fresh water sediments of Lake Constance (Lauterborn, 1907), the Neva river at St. Petersburg (Wisłouch, 1912), in the Rhine and in Baltic coastal lagoons (Kolkwitz, 1912), and in Lake Erie (Maier, 1980). Many of these small-scale habitats are affected by environmental change and human impact, with the result that many older sampling sites do not exist today (Maier and Preissner, 1979). Recently, mats of freshwater *Thioploca* spp. have been found in Lake Baikal in Siberia (Namsaraev et al., 1994; Zemskaia et al., 2001), in Lake Ontario between the United States and Canada (Dermott and

Legner, 2002) and in Lake Biwa, Japan (Nishino et al., 1998; Kojima et al., 2003). These extensive freshwater *Thioploca* mats offer the opportunity to study freshwater *Thioploca* spp. in similar detail as their marine counterparts.

Identification and Taxonomy

The genera *Beggiatoa* and *Thioploca* are recognized primarily on the basis of their filamentous morphology and, in the case of *Thioploca*, their growth pattern as bundles of filaments surrounded by a gelatinous sheath. For *Beggiatoa*, the filament lengths are from a few μm to 10 cm; the cell and filament diameter range between ca. 1–200 μm . For *Thioploca*, filaments reach 2–5 cm in length, and reach diameters of 2.5–80 μm . Another reliable characteristic is the ability to oxidize sulfide and to store the intermediate oxidation product, elemental sulfur, in small intracellular, highly refractory and conspicuous sulfur globules. This character separates the genus *Beggiatoa* from the filamentous genus *Vitreoscilla*, which is obligately heterotrophic and does not form intracellular sulfur globules by sulfide oxidation. The genus *Beggiatoa* differs from the filamentous genus *Thiothrix* by the specific attachment of the latter via specialized “hold-fast” cells (often in a rosetta-like growth pattern) of the latter, and is also phylogenetically distinct (Teske et al., 1995; Howarth et al., 1999).

The genera *Beggiatoa* and *Thioploca* harbor considerable morphological and physiological diversity that is not adequately represented by the small number of recognized species. Within the genus *Beggiatoa*, three major phenotypically defined groups can be distinguished: 1) the heterotrophic nonvacuolate freshwater strains with thin filament diameter, represented by several well-studied strains: The type strain of the genus *Beggiatoa* (B18LD; Mezzino et al., 1984), B15LB (Strohl et al., 1982), OH-75-2a (Nelson and Castenholz, 1981b; Nelson and Castenholz, 1981a), and L1401-13 (Pringsheim, 1964; Kowalik and Pringsheim, 1966; Fig. 6); 2) the autotrophic nonvacuolate marine strains with thin filament diameter, represented by the facultatively autotrophic strain MS-81-6 and by the obligately autotrophic strains MS-81-1c (Nelson et al., 1982b; Nelson et al., 1986a; Nelson and Jannasch, 1983; Hagen and Nelson, 1996; Hagen and Nelson, 1997; Fig. 7); and 3) the large, vacuolated, nitrate-accumulating autotrophic marine *Beggiatoa* strains which so far remain uncultured (Hinze, 1901; Jannasch et al., 1989b; Nelson et al., 1989c; McHatton et al., 1996; Fig. 8).

In contrast to *Beggiatoa* filaments, *Thioploca* filaments aggregate into bundles that are enclosed by a robust polysaccharide sheath,

Fig. 6. Light micrograph of a pure culture of freshwater strain OH-75-2a, stationary phase, grown in liquid DTA medium. Some filaments are devoid of refractile S₀ globules. Nonrefractile inclusions are probably poly- β -hydroxybutyrate (PHB) granules. Bar = 5 μm . Phase contrast. Courtesy of Douglas Nelson.

the defining character of the genus *Thioploca* (Maier, 1989). The ensheathed bundles, which contain a few to a few dozen of these filaments, occur mostly embedded in sediments and plant detritus; they can reach lengths of several centimeters in large *Thioploca* species and thus form

Fig. 8. Large marine *Beggiatoa* spp. from the Guaymas Basin and Monterey Bay. A) Filament tip of a very large, nitrate-accumulating *Beggiatoa* from the Guaymas Basin hydrothermal vents. The filament is ca. 160 μm in diameter. The highly refractory sulfur globules outline the disk-like cells within the filament. Dark field microphotograph. B) Two *Beggiatoa* spp. from Guaymas under ultraviolet (UV) light. The larger species (ca. 100 μm filament diameter) is fluorescing blue, the smaller species (ca. 35 μm filament diameter) yellow-orange. UV epifluorescence microphotograph. Courtesy of Andreas Teske. one of the largest prokaryotic structures. These bundles are conspicuous not only by their large size, but also by their whitish or beige color, and have indeed reminded several investigators of slightly overcooked angel hair pasta, leading to the nickname “spaghetti bacteria.” In the genus *Thioploca*, no cultured species exist. Here, at

least two phenotypic groups can be distinguished: 1) The freshwater or brackish *Thioploca* spp. with thin filament diameter and no visible or only modest vacuolation (Lauterborn, 1907; Wislouch, 1912; Maier and Murray, 1965; Fig. 9); and 2) the large, highly-vacuolated, nitrate-accumulating autotrophic marine species *Thioploca chileae* and *Thioploca araucae* (Maier and Gallardo, 1984; Fig. 10).

For both *Beggiatoa* and *Thioploca*, these classifications almost certainly hide as much diversity as they reveal and should not be regarded as complete but rather represent working definitions on the basis of current insufficient knowledge. Exceptions and borderline cases exist, such as the recent demonstration that an autotrophic freshwater *Beggiatoa* sp. does exist (Grabovich et al., 1998; Grabovich et al., 2001; Patrinskaya et al., 2001), and the observation that *Thioploca ingrica* has cytoplasmic vacuolation. Although

examination of specimens from Danish fjords did not reveal nitrate accumulation (L. P. Nielsen, personal communication), high intracellular nitrate accumulation, by four orders of magnitude, has been found in small freshwater *Thioploca* spp. (2–5 µm diameter) from underwater thermal vents in Lake Baikal (Zemskaya et al., 2001).

Further, the generalization that filamentous morphology prevails in these groups has exceptions. *Thiomargarita namibiensis*, a close phylogenetic relative of the large marine *Thioploca* species, occurs as a series of large, balloon-like cells that are lined up in short chains within a shared sheath, or may exist as individual cells, but not as filaments (Schulz et al., 1999; Fig. 11).

Thioploca species have been described solely based on filament diameter of consistently recurring size classes of specimens collected in the environment (Table 1); these data were later complemented by 16S rRNA sequences. The identification and recognition of species based on morphological and genotypic characteristics of specimens collected from the environment is unusual, but this system has been applied in several cases to morphologically conspicuous microorganisms that can be reproducibly obtained from natural source materials (*Epulopiscium*

fishelsoni, *Thiomargarita namibiensis*, *Thiovulum majus*, and *Achromatium oxaliferum*). For *Beggiatoa*, the type species *Beggiatoa alba*, a freshwater, non-autotrophic isolate, remains so far the only recognized species (Mezzino et al.,

Fig. 11. Light micrograph of a typical ensheathed chain of *Thiomargarita namibiensis* cells (0.1–0.15 mm in diameter). Courtesy of Heide Schulz.

1984). This is at odds with physiological, genomic and morphological evidence for considerable diversity within the genus *Beggiatoa*. Several important freshwater and marine *Beggiatoa* strains with contrasting physiological properties (from obligately autotrophic to heterotrophic growth) have been investigated and described in detail (Table 1). Also, discrete size classes of *Beggiatoa* filaments have been described early (Klas, 1937), and the identification of ever larger size classes has extended the size spectrum of filament diameters to ca. 200 μm (Nelson et al., 1989c; Larkin and Henk, 1996). For uncultured *Beggiatoa* spp., a consistent taxonomy could be developed on the basis of reproducibly defined morphotypes correlated with 16S rRNA sequences.

For both *Beggiatoa* and *Thioploca*, marine and freshwater habitats harbor different physiological and morphological types (Table 1). In contrast to small freshwater *Thioploca* with filament diameters in the range of 1–9 μm , marine *Thioploca* species reach diameters of at least 20–40 μm . Similarly, marine *Beggiatoa* populations can reach filament diameters of 100–200 μm (Table 1). Large *Thioploca* and *Beggiatoa* spp. have large cytoplasmic vacuoles that comprise ca. 80–90% of the cellular biovolume (Maier et al., 1990; McHatton et al., 1996). So far, very high intracellular nitrate concentrations of ca. 100–500 mM have been found in all environmental populations of large, vacuolated *Beggiatoa* and *Thioploca*, and in a population of freshwater *Thioploca* that match the size class of *Thioploca ingrica* (Zemskaya et al., 2001). These *Thioploca* and *Beggiatoa* species accumulate and store nitrate intracellularly, most likely in their vacuoles. On the basis of these phenotypic and physiological similarities, large, vacuolated, nitrate-accumulating *Thioploca* and *Beggiatoa* populations could be specifically related to each other and to *Thiomargarita*. This grouping is confirmed by 16S rRNA sequence analyses that show a monophyletic branch for these populations. Implicitly, sheath formation, the classical character to separate *Beggiatoa* from *Thioploca*, appears to be phylogenetically shallow and variable (Teske et al., 1995; Teske et al., 1999; Ahmad et al., 1999b). These physiologically and phylogenetically consistent characters may in the future provide a basis to revise the delineation between the genera *Beggiatoa* and *Thioploca*.

Cell Structure

Narrow *Beggiatoa* filaments examined in pure culture (2–5 μm width) are typically composed of cylindrical cells, with lengths from 1.5–8 \times their width (Faust and Wolfe, 1961; Scotten and

Stokes, 1962; D. Nelson, unpublished observations). However, crosswalls are rarely visible in cultured cells filled with poly- β -hydroxybutyrate (PHB) or elemental sulfur (Figs. 6 and 7). Trichomes may exceed 1 cm in length when actively growing in semisolid medium. Terminal cells are rounded in all cultured strains. Exhausting of nutrients results in trichome breakage at necridia or “sacrificial” cells (Pringsheim, 1964; Strohl and Larkin, 1978a) to produce trichomes as short as 3–10 μm in length. The wider filaments of large marine *Beggiatoa* are disk-shaped with cell lengths from 0.10–0.90 \times their cell width (Table 1). Cells of large, marine *Beggiatoa* filaments are hollow, i.e., composed of a thin cylinder of cytoplasm surrounding a large central vacuole. This extensive vacuolation, combined with high intracellular nitrate concentration, is consistently found in large *Beggiatoa* and *Thioploca* (Janasch et al., 1989b; Nelson et al., 1989c; Larkin and Henk, 1996; McHatton et al., 1996).

The few *Beggiatoa* strains tested are Gram negative both phylogenetically and by staining; however, they have unusual cell wall structures. Figure 12 shows a schematic diagram of *Beggiatoa alba* B15LD that indicates that only the inner layer of the cell wall (presumably murein) plus the cell membrane participate in septation. The outer envelope layers do not participate in cross-wall formation but are apparently continuous over the entire filament length (Strohl et al., 1982).

Three types of inclusions have been reported for various *Beggiatoa* strains: PHB (Pringsheim, 1964; Strohl and Larkin, 1978b; Strohl et al., 1982), polyphosphate (Maier and Murray, 1965; Strohl and Larkin, 1978b), and sulfur (Winogradsky, 1887; Strohl et al., 1981b; Strohl et al., 1982). The reports of polyphosphate should be regarded as tentative because the staining technique employed is nonspecific (Krieg and Hylleberg, 1976). Production of PHB appears, on the other hand, to be a universal feature of the heterotrophic freshwater strains examined. Numerous cell inclusions that most likely are PHB were also found by transmission electron microscopy (TEM) in the fresh and brackish water species *Thioploca ingrica* (Kojima et al., 2003). Interestingly, PHB deposition in *Beggiatoa* seems to correlate primarily with high aeration (Pringsheim, 1964), and it can account for up to 50% of total dry weight under these conditions in the absence of sulfide (Güde et al., 1981).

The sulfur inclusions of *Beggiatoa* are periplasmic in location, being enclosed in invaginations of the cell membrane (Fig. 12). The sulfur globules in the specific strain diagrammed here are enclosed within a multilayered sulfur inclusion envelope of 12–14 nm thickness (Strohl et al., 1982), while in other strains the S₀ globule enve-

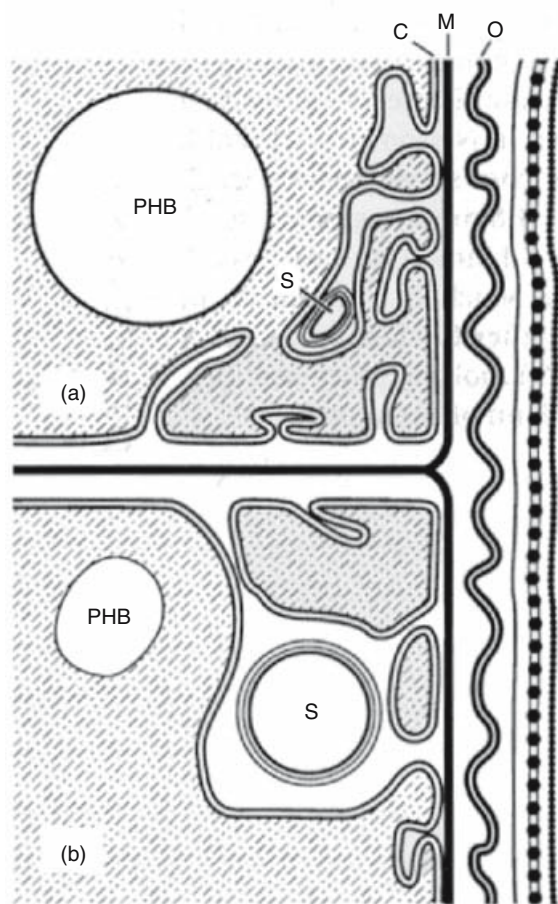

Fig. 12. Ultrastructure of *Beggiatoa alba* strain B15LD (ATCC 33554). Symbols: C, cell membrane; M, presumed murein layer; O, presumed outer membrane layer; S, globule of S₀; PHB, poly-β-hydroxybutyrate granule. A) Note large PHB inclusion and rudimentary S₀ globule typical of cells grown in acetate-supplemented mineral medium. B) Note small PHB inclusion and large S₀ globule typical of cells grown in the presence of sulfide or thiosulfate and a low concentration of acetate. Adapted from Strohl et al. (1982).

lope appears to be composed of a single protein layer 4–5 nm thick (Strohl et al., 1981b). The extraction of S₀ globules with solvents such as pyridine and their refractile appearance when intact cells are viewed under phase contrast microscopy have proven very useful in confirming their presence (Skerman et al., 1957). As shown schematically (Fig. 12), *Beggiatoa* cells grown in the absence of reduced sulfur compounds apparently contained small, rudimentary S₀ inclusion envelopes (Strohl et al., 1982). Since dehydration solvents (e.g., ethanol) necessary for preparation of electron microscopy dissolve the S₀, it is difficult to determine whether the rudimentary inclusions completely lack elemental sulfur. The sulfur globules consist of fine grained, microcrystalline elemental sulfur in the common,

stable S8 ring configuration (Pasteris et al., 2001; Prange et al., 2002) without significant additions of other elements (Lawry et al., 1981); they are surrounded by extensions of the cytoplasmic membrane plus an inner sulfur inclusion envelope (Lawry et al., 1981; Strohl et al., 1981b). The cyclooctasulfur globules of *Beggiatoa alba* (strain DMSZ 1416) and of *Thiomargarita namibiensis* differ from sulfur globules produced by other sulfur oxidizers, such as polythionate sulfur globules of *Acidithiobacillus thiooxidans*, and sulfur chain-dominated sulfur globules of anoxygenic phototrophs (Prange et al., 2002); the differences in sulfur speciation probably reflect different sulfur deposition pathways.

At present, no ultrastructural markers are known that separate *Beggiatoa* from *Thioploca* cells and filaments. In other words, a *Thioploca* filament outside its sheath is indistinguishable from a *Beggiatoa* filament. The sheath formed by *Thioploca* spp, while not a structural feature of the cell, is a taxonomically useful marker and structural characteristic that can distinguish *Thioploca* species. The sheaths of *Thioploca ingrica* strains from fresh and brackish water show conspicuous constricted zones at random intervals (Wislouch, 1912; Kojima et al., 2003); this characteristic has not been found in marine *Thioploca* species. *Thioploca* sheaths appear to have a striated texture that runs parallel to the *Thioploca* filaments; epibiotic filamentous bacteria on and within the sheath matrix tend to be aligned parallel to the sheath striation and the *Thioploca* filaments (Fukui et al., 1999). Within a marine *Thioploca* population, the cell dimensions indicate two clearly separated morphotypes, the long-cell and the short-cell morphotype, with ratios of average cell length to trichome diameter above and below 0.48 (Schulz et al., 2000).

Isolation and Cultivation

Selective Enrichments

The most consistently successful enrichments for *Beggiatoa* spp. have been made as follows: The bottom of a shallow pan or aquarium (approximately 30 × 30 × 12 cm) is covered with a few centimeters of sand. CaSO₄ (approx. 20 g) and K₂HPO₄ (a few grams) are then added, along with a source of complex organic polymers such as seaweed or shredded paper. This is covered with several centimeters of sulfide-rich marine mud, and then enough seawater to cover the entire enrichment to a depth of 1–2 cm is added. Covering the pan with aluminum foil or incubating in a dark place minimizes competition with phototrophic bacteria. The enrichment is certain

to contain the proper sulfide-oxygen interface somewhere in the vessel if air is introduced near the sediment surface using an air stone. Water lost by evaporation should be replaced by distilled water. Alternatively, a slow steady flow of freshly aerated seawater, with a drain maintaining a constant level, will provide the necessary O_2 . A similar freshwater enrichment inoculated with mud from a sulfur spring and maintained on a light-dark cycle (10h:14h) provided viable tufts of *Beggiatoa* spp. for almost one a year (Nelson and Castenholz, 1982a). Sewage treatment plants are also an excellent source of enrichment material (Burton and Lee, 1978; Williams and Unz, 1985).

Another type of enrichment has a long historical association with *Beggiatoa* and is based on the use of extensively extracted dried grasses or hay in an otherwise mineral medium (Cataldi, 1940). The complex polymers such as cellulose residues in the material presumably fuel sulfate reduction localized near the surface of the grasses. This, in turn, provides the hydrogen sulfide necessary to enrich for *Beggiatoa*. The grasses also serve as a physical substrate for these gliding bacteria. Inclusion of soil extract and the enzyme catalase appear to enhance the rate and success of this enrichment (Joshi and Hollis, 1976; Strohl and Larkin, 1978b).

Without attempts at enrichments or pure culture isolation, *Beggiatoa* mats growing on sulfidic sediments kept alive for some time in an aquarium in their natural sediment. The development of a marine *Beggiatoa* mat in the laboratory unfolded over 10 days and revealed a succession of different *Beggiatoa* size classes, with larger types replacing the smaller ones (Bernard and Fenchel, 1995).

Pure Culture Isolation

Three different approaches have been used to isolate and to maintain *Beggiatoa* strains in pure culture.

ISOLATIONS ON AGAR PLATES Tufts of *Beggiatoa* filaments are collected from the environment or an enrichment with a Pasteur pipette or pointed forceps, washed by multiple rinses in sterile washing solution, and placed on the center of a well-drained agar plate (0.8–1.2% agar) that contain dilute organic substrates, such as small amounts (1–0.25% w/v) of peptone or yeast extract. Growing filaments that move away from the central inoculum are cut out on agar blocks and are used as inoculum for new agar plates (Pringsheim, 1967). These procedures have led to the isolation of heterotrophic *Beggiatoa* strains. Modifications of this technique were aimed at reducing the organic carbon content of

the agar medium by using defined mineral media (Nelson and Castenholz, 1981a) to select against heterotrophic contaminants, and to favor enrichment and isolation of autotrophic *Beggiatoa*. Agar plates (made with filtered seawater, trace elements, vitamin mix, and supplemented with sodium sulfide, ammonium sulfate, sodium thiosulfate, and sodium acetate) were used for the isolation of marine *Beggiatoa* strains that in subsequent tests showed autotrophic growth (Nelson et al., 1982b). While the isolation of freshwater strains has typically employed agar-gelled medium equilibrated with full air, the use of bell jars to provide a micro-oxic atmosphere has, thus far, been essential for isolation of autotrophic marine strains.

For the freshwater strains currently available, isolation was performed under oxic conditions (air atmosphere) on a variety of media that contained a low concentration of a single organic compound, principally acetate, lactate or glucose, and sometimes a reduced sulfur source, such as Na_2S or thiosulfate (Strohl and Larkin, 1978b; Nelson and Castenholz, 1981a; Williams and Unz, 1985). A representative medium is shown here:

DTA Medium

ND stock solution	50 ml
$(NH_4)_2SO_4$	0.13 g
Sodium acetate	0.68 g
K_2HPO_4	0.027 g
$Na_2S_2O_3 \cdot 5H_2O$	0.50 g
$CaCl_2$	0.10 g
Distilled water	950 ml
Agar	8–12 g

ND Stock Solution (Castenholz, 1988)

Distilled water	1000 ml
NTA (nitrilotriacetic acid)	2.0 g
Micronutrient solution	10 ml
$FeCl_3$ solution (0.29 g/liter)H	20 ml
$CaSO_4 \cdot 2H_2O$	1.2 g
$MgSO_4 \cdot 7H_2O$	2.0 g
NaCl	0.16 g
Na_2HPO_4	1.4 g
KH_2PO_4	0.72 g

Micronutrient Solution

Distilled water	1000 ml
H_2SO_4 (concentrated)	0.5 ml
$MnSO_4 \cdot H_2O$	2.28 g
$ZnSO_4 \cdot 7H_2O$	0.50 g
H_3BO_3	0.50 g
$CuSO_4 \cdot 5H_2O$	0.025 g
$Na_2MoO_4 \cdot 2H_2O$	0.025 g
$CoCl_2 \cdot 6H_2O$	0.045 g

The pH is adjusted to 7.0 prior to autoclaving. As in the marine isolations, it is important that the surface of the agar is dry. For purification of single filaments from enrichment-derived tufts, lowering the acetate concentration to 0.5 mM for the initial dispersal of filaments may minimize contamination.

A sulfide-oxygen gradient medium based on DTA medium has proved effective for maintaining freshwater strains because they require infrequent transfer. The sulfide concentration of the butt should be reduced to 3–4 mM, and thiosulfate can be omitted from the top agar.

ISOLATION OF LITHOTROPHIC MARINE STRAINS The known marine strains of *Beggiatoa* are obligate microaerophiles that were isolated under micro-oxic conditions (4 kPa O₂) on medium supplemented with sodium sulfide and sodium acetate. Subsequently, it was realized that all strains will grow luxuriantly in sulfide-gradient medium (described below) in the absence of added organics.

The following procedure ensures a marine basal medium (J3) free of precipitates.

J3 Medium

Solution 1

Prefilter (Whatman #1 or Gelman GF/F) then filter (0.45 µm) 500 ml of aged natural seawater (salinity 3.2–3.5%).

Solution 2

Dissolve 9.0 g of agar in 200 ml of distilled water.

Solution 3

Mix the following ingredients: NH₄NO₃, 0.06 g; trace elements (SL8; Pfennig and Biebl, 1981), 0.75 ml; and mineral stock, 50 ml. The mineral stock contains per liter: K₂HPO₄, 0.52 g; Na₂MoO₄, 0.05 g; FeCl₃ · 6H₂O, 0.29 g; Na₂S₂O₅ (sodium pyrosulfite), 0.75 g; and phenol red, 10 ml of a sterile solution (0.5%, Gibco).

Autoclave solutions 1, 2 and 3 separately in Erlenmeyer flasks. After cooling to 50°C, aseptically combine in the solution 2 vessel (volume >750 ml). Then supplement with 0.2 ml of Va vitamin solution, which contains (in mg per liter): B12, 1; thiamine, 200; biotin, 1; folic acid, 1; *para*-aminobenzoic acid, 10; nicotinic acid, 100; inositol, 1; and calcium pantothenate, 100.

J-TS Medium

J3 basal medium is amended to produce an isolation medium (J-TS) by adding the following sterile stocks, with final concentrations in parentheses:

Solution 1

7.5 ml of 200 mM Na₂S₂O₃ (2 mM)

Solution 2

3.75 ml of freshly neutralized 200 mM Na₂S (1 mM).

Autoclave as a basic solution, which is quite stable against autooxidation, and then neutralize with an equimolar quantity of sterile HCl just prior to use.

Solution 3

15 ml of 1 M NaHCO₃ (20 mM). To make this stock, autoclave 8.4 g of NaHCO₃ (dry) and add 100 ml sterile water when cool.

Immediately after solidification, incubate plates in a bell jar for 24 h or more under anoxic conditions (99.5% N₂, 0.5% CO₂), with desiccant present to absorb water evaporating from the surface of the medium. The medium is buffered by the bicarbonate in conjunction with the level of atmospheric CO₂. After inoculation with a tuft of *Beggiatoa* spp., place plates in a micro-oxic atmosphere (0.5% CO₂; 0.2% O₂; and 99.3% N₂). Exposing the

medium and bacteria to full air for approximately 20 min every day or two, as needed for inoculation or single-filament isolations, poses no problem to the success of the technique. Pure cultures resulting from repeated single-filament isolations can be maintained in sulfide-oxygen gradient media (see ISOLATION USING LIQUID MEDIA).

ISOLATION USING LIQUID MEDIA Liquid media can be used for enrichment, MPN enumeration, and bulk cultivation of *Beggiatoa*. In an extensive study, Strohl and Larkin (1978b) have tested several liquid media formulations for isolation and MPN enumeration of heterotrophic *Beggiatoa* filaments from organic-rich freshwater ditches and lakes. They obtained the best results with a soil extract amended with 0.05% (w/v) acetate, 15–35 U of catalase per ml, and 1% (w/v) hay extract. Early attempts to use liquid media for bulk cultivation (Kowallik and Pringsheim, 1966) had already demonstrated the importance of small amounts of carbon substrates, either soil or hay extracts or small amounts of acetate, for successful cultivation of heterotrophic or mixotrophic freshwater *Beggiatoa*. The type species and strain (*Beggiatoa alba* str. B18LD) and related strains are generally grown in media that include a salt base, acetate as carbon source, and variable yeast extract and sulfide additions (Mezzino et al., 1984; Schmidt et al., 1986). Only recently, marine autotrophic *Beggiatoa* strains were cultured in bulk in a defined liquid mineral medium with thiosulfate as sole energy source and CO₂ as sole carbon source, under micro-oxic conditions under aeration with 0.25% O₂ (v/v) in the gas phase (Hagen and Nelson, 1996). The cultivation of a freshwater *Beggiatoa* strain in liquid mineral medium on thiosulfate and HCO₃[–] required dissolved oxygen concentrations in the range of 3–16 µM (0.1–0.5 mg O₂/liter; Patrinskaya et al., 2001).

ISOLATION AND CULTIVATION IN GRADIENT MEDIA After single-filament isolations on solid agar medium yielded pure cultures of nonvacuolate *Beggiatoa* spp., autotrophic strains were most easily maintained and propagated in sulfide gradient tubes (Nelson and Jannasch, 1983), where sulfide-rich agar plugs are overlaid with sulfide-free soft agar. For cultivation of estuarine strains, the soft agar medium is based on a 2/3-strength natural seawater medium that lacks reduced sulfur compounds but includes trace elements and vitamin mix, and ammonium nitrate (J2 medium). Tubes were loosely capped to permit exchange of headspace gasses with the atmosphere. The resulting two layers of agar contain opposed sulfide and oxygen gradients, that allow the growth of a well-defined *Beggiatoa* layer at the sulfide-oxygen

interface (Nelson et al., 1986b; Nelson et al., 1986a). Propagation of vent or seep (fully marine) strains of *Beggiatoa* may require medium of a higher salinity.

CONSTRUCTION OF GRADIENT MEDIUM Marine gradient medium (JG8) was constructed as follows: First, 4 ml of J3 medium (pH 8.4; 1.5% agar; and NaHCO_3 concentration lowered to 2.0 mM) supplemented with freshly neutralized Na_2S was solidified in the bottom of a 16 × 150 mm screw-capped tube. An initial sulfide concentration of 8 mM in this butt has proven satisfactory for all isolates tested. The thiosulfate present in the isolation medium need not be included because the tube geometry provides a sustained flux of sulfide for several weeks. The butt was then overlaid with 8.0 ml of semi-solid J3 medium (0.25% agar; NaHCO_3 concentration lowered to 2.0 mM; and no sulfide or thiosulfate). At this point the gradient of soluble sulfide (neglecting convective mixing) is theoretically a “step-gradient,” i.e., all of the sulfide will be below the interface between the sulfidic agar plug and the sulfide-free overlay agar. The air headspace reservoir in the top 8 ml of the tube constitutes an oxygen reservoir. Molecular diffusion and nonbiological reaction between sulfide and oxygen gradually alter the gradient shapes as described in detail elsewhere (Nelson et al., 1986b; Nelson et al., 1986a).

Aging new gradient media for 2–3 days prior to inoculation establishes a sulfide-oxygen interface that is quite stable in both position and rates of nutrient flux. The interface is located near the top of the agar column, but the extent of sulfide and oxygen overlap is roughly 6–7 mm in uninoculated medium (Nelson et al., 1986a) as compared with 0.2 mm or less in *Beggiatoa* cultures. Whether inoculated at the surface of this medium or stabbed throughout the upper few centimeters, the filaments rapidly proliferate at the sulfide-oxygen interface, forming a marked layer or “plate,” of 1 mm (maximum thickness). Gliding motility and negative chemotactic responses allow these bacteria to track this interface as it slowly descends, owing to the gradual depletion of the sulfide reservoir.

CULTIVATION OF THIOPLOCA Currently, no pure cultures or enrichments of *Thioploca* species or strains exist. All biochemical, physiological and molecular work has been performed on *Thioploca* filaments collected from their natural environment, marine or freshwater sediments. Natural *Thioploca* populations can be kept alive in the laboratory for months or even years. Maier (1989) described the following procedures for cultivation of freshwater *Thioploca*. These may be maintained in jars overlaid with

Fig. 13. Gradient culture of marine *Beggiatoa* spp. Photo of Aarhus gradient culture setup. The oxygen profile in a gradient culture of *Beggiatoa* spp. is determined with an oxygen microelectrode mounted onto a micromanipulator (Nelson et al., 1986b). The whitish *Beggiatoa* plate is visible near the surface of the gradient culture, and its position is indicated by the point light source. Courtesy of Douglas Nelson.

tap water at 8–20°C in the dark; at approximately yearly intervals, a few stems of extracted grass (Scotten and Stokes, 1962) may be stuck into the sediment and *Thioploca* often colonizes these stems. Alternatively, 0.2–0.3 g of pulverized extracted hay is autoclaved in 60 ml of tap water in 125-ml Erlenmeyer flasks and inoculated with 4–10 ml of sediment (Maier, 1980). After a month of undisturbed incubation at room temperature to avoid periods of maximum H_2S development, *Thioploca* bundles are added and incubation continues for many weeks with intermittent inspection.

Attempts to enrich marine *Thioploca* spp. have met with little success. They may be maintained for months in undisturbed cores sampled from the natural populations and kept near the in-situ temperature of 13°C in a basin of anoxic seawater with nitrate added (H. Schulz, personal communication). Physiological studies with harvested, large marine *Thioploca* filaments required careful handling of the filaments and avoidance of oxygen and air exposure to avoid significant losses in enzymatic activities (Otte et al., 1999). Future cultivation approaches have to take the sensitivity of *Thioploca* to high sulfide concentrations and to oxygen exposure into account, and maintain the delicate balance of sulfide, nitrate and oxygen concentrations that characterizes its natural habitat (Hüttel et al., 1996; Schulz et al., 2000).

STRAIN MAINTENANCE Freshwater and marine strains of *Beggiatoa* spp. are readily maintained in sulfide-oxygen gradient media. The fact that oxygen and sulfide gradients are “self-forming” (Nelson et al., 1986a) coupled with the chemotactic motility of the bacteria, which directs them to the proper micro-environment, makes this approach especially attractive for obligately microaerophilic strains. A low concentration of acetate must be provided for the strains that do not show lithoautotrophic capacity. For the typical medium geometry employed (Nelson, 1992), transfers to new tubes of gradient medium should be made every 2–3 weeks, and medium should be kept no more than 4–6 weeks or the sulfide flux will be greatly diminished. Sustained propagation of heterotrophic freshwater strains on agar plates in the presence of full air is straightforward. By contrast, propagation of marine strains on agar plates under micro-oxic regimes in bell jars is best reserved for initial isolation and any required re-purification steps. Cryopreservation of strains beyond 6 months to one year has proved problematic (D. C. Nelson, unpublished observation).

Biochemical and Physiological Properties

Carbon Metabolism

Carbon assimilation processes and pathways of *Beggiatoa* came under investigation shortly after Winogradsky began to develop the concept of microbial chemolithoautotrophy, based on his initial investigations with this organism (Winogradsky, 1887). Almost a century later, the first clearly autotrophic *Beggiatoa* strains were isolated in pure culture (Nelson et al., 1982b; Nelson and Jannasch, 1983). In autotrophic *Beggiatoa* strains, carbon fixation occurs via the Calvin cycle, as judged by the activity level and regulation of RuBPC/O (Ribulose-1,5-bisphosphate carboxylase/oxygenase). In the obligately autotrophic strain MS-81-1c, RuBPC/O cannot be repressed by acetate additions and is always active at similar levels. The facultatively autotrophic strain MS-81-6 tightly regulates autotrophic vs. heterotrophic growth. Acetate additions reduce the activity of RuBPC/O to a small fraction of its activity in organic-free medium, and increase the activity of 2-oxoglutarate dehydrogenase (Hagen and Nelson, 1996), a key enzyme of the citric acid cycle, opens the way to respiratory oxidation of C2 substrates. Under autotrophic growth conditions, 2-oxoglutarate dehydrogenase is not expressed thus interrupting the citric acid cycle at the stage of 2-oxoketoglutarate. As a result, autotrophically

fixed carbon is not oxidized but used for synthesis of cellular compounds. Even the obligately autotrophic *Beggiatoa* str. MS-81-1c increases its growth yield by ca. 20% after addition of acetate, indicating that acetate can be used as an auxiliary carbon source for the synthesis of cell material in a manner analogous to other chemolithoautotrophic sulfur-oxidizing bacteria (Hagen and Nelson, 1996).

Strong evidence for autotrophic potential has been found in uncultured, large marine *Beggiatoa* spp. Freshly collected samples of large, marine *Beggiatoa* from the Guaymas Basin hydrothermal vents showed significant RuBPC/O activity; some of these vent populations possessed RuBPC/O that was active at 50°C and, hence, appear to be moderate thermophiles (Nelson et al., 1989c). Uncultured populations of large *Beggiatoa* from cold sulfide seeps in the Monterey Canyon also showed reasonably high RuBPC/O activity (McHatton et al., 1996; Table 2). The ^{13}C -isotopic signature of large *Beggiatoa* filaments from cold seep sediments in the Gulf of Mexico was consistent with carbon assimilation by the Calvin cycle (Larkin et al., 1994). *Beggiatoa* mats growing on and within sediment layers with active sulfate-dependent methane oxidation take up ^{13}C -depleted CO_2 derived from methane oxidation and show the isotopically light signature ($\delta^{13}\text{C}$ in the range of -50 to -60 ‰) of partially methane-derived biomass (Paull et al., 1992; Orphan et al., 2002).

In freshly collected natural samples of marine *Thioploca* spp., CO_2 uptake occurred at rates similar to those of large hydrothermal vent *Beggiatoa* (Otte et al., 1999). Acetate was incorporated into *Thioploca* filaments at a rate roughly equal to that of CO_2 , with no apparent terminal oxidation, suggesting that large marine *Thioploca* spp. are facultative chemolithoautotrophs (Otte et al., 1999). The two dominant Chilean *Thioploca* species (*Thioploca chileae* and *T. araucae*) were both able to incorporate carbonate as well as acetate and amino acids (Maier and Gallardo, 1984), but the conclusions of that study must be tempered by the observation that the inorganic carbon was labeled to a much lower specific activity than the organic substrates (Nelson, 1989a).

HETEROTROPHIC GROWTH In contrast to autotrophic marine *Beggiatoa* spp., all but one freshwater *Beggiatoa* strain isolated so far required various organic substrates for growth, at least in small amounts (Faust and Wolfe, 1961; Scotten and Stokes, 1962; Pringsheim, 1964; Burton et al., 1966; Kowalik and Pringsheim, 1966; Strohl and Larkin, 1978; Nelson and Castenholz, 1981a; Nelson and Castenholz, 1981b). Most *Beggiatoa* strains examined can grow with ace-

tate as a sole source of carbon and energy. Heterotrophically cultured freshwater *Beggiatoa* strains that were transferred to liquid culture with H₂S as energy source, grew much better with acetate additions in the range of 0.01–0.0001% (w/v; Kowallik and Pringsheim, 1966). All strains of the type species *Beggiatoa alba* (B18LD, B15LD, and B25RD) grew well in the presence of sulfide and additions of 0.001–0.05% acetate (Mezzino et al., 1984). *Beggiatoa alba* B18LD quickly incorporated ¹⁴C-labelled acetate into a wide range of cellular and storage compounds. The strain had possessed the ability to oxidize acetate (both C-atoms) to CO₂ and to use it as an energy source. Also, acetate significantly increased the capability of this strain to assimilate CO₂, probably through anaplerotic reactions of the tricarboxylic acid (TCA) cycle (Strohl et al., 1981a).

In the heterotrophic *Beggiatoa* strains that have been tested, carbon substrate utilization patterns are generally consistent with a functional TCA cycle. A detailed study of heterotrophic nutrition of *Beggiatoa* strain OH-75-2a indicated a functional TCA cycle with a

glyoxylate bypass (Nelson and Castenholz, 1981a). *Beggiatoa* str. OH-75-2a can grow on acetate, ethanol, lactate, pyruvate with a small addition of yeast extract, and on TCA cycle intermediates in combination with acetate. A detailed enzymological study with another chemoheterotrophic strain, "*Beggiatoa leptomitiformis*" D-405, confirmed the presence of all essential TCA cycle enzymes during growth on succinate (Grabovich et al., 1993). Furthermore, the presence of enzymes defining the glyoxalate-bypass were detected during growth on acetate or lactate.

Although reliable data are available on heterotrophic and autotrophic capabilities of *Beggiatoa* spp., there is no conclusive evidence for mixotrophic growth of *Beggiatoa*. The term "mixotrophic" is used here in the sense that heterotrophically growing *Beggiatoa* spp. which oxidize organic compounds can to a certain degree substitute sulfide or other reduced sulfur compounds as electron donors. In this way, they can utilize a greater portion of their available (and limited) organic carbon sources for cell material synthesis instead for terminal oxidation. This

type of chemolithoheterotrophy does not require autotrophic CO₂ fixation capabilities, and would be generally possible for heterotrophic *Beggiatoa* strains. The idea is intriguing, since mixotrophic growth should broaden the ecophysiological flexibility of *Beggiatoa* and *Thioploca* spp. in nature (Pringsheim, 1967; Strohl and Schmidt, 1984). So far, quantitative experiments with the heterotrophic strain OH-75-2a have shown that the increased growth yield in dry weight is accounted for by the weight of the accumulated sulfur globules, not by an increase in cellular biomass (Nelson and Castenholz, 1981b). Attempts to demonstrate mixotrophy showed experimental shortcomings and need to be revisited (Güde et al., 1981; see also Nelson and Jannasch, 1983). Sulfur oxidation in heterotrophic strains does not proceed efficiently beyond the stage of elemental sulfur; and the energy-yielding oxidation of sulfur to sulfate is not exploited for mixotrophic growth in the best-studied freshwater strains (Nelson and Castenholz, 1981b; Schmidt et al., 1987). These findings are complemented by a survey of the sulfur-oxidizing enzymes in the heterotrophic freshwater strain OH-75-2a, which does not show activity of sulfite-oxidizing enzymes (no APS reductase and no ADP sulfurylase) that enable the oxidation of sulfite to sulfate (Hagen and Nelson, 1997). However, this strain shows activity of AMP-independent, membrane-associated sulfite:acceptor oxidoreductase, one of the enzymes required for generating energy from the oxidation of reduced sulfur compounds. The facultatively autotrophic marine *Beggiatoa* strain MS-81-6 is most likely mixotrophic with regard to both carbon and energy metabolism (Hagen and Nelson, 1996).

Nothing is known about heterotrophic growth requirements and substrates for *Thioploca*. One may speculate that the smaller, freshwater *Thioploca* species correspond in their physiology to small freshwater heterotrophic *Beggiatoa*; research in this area is lacking so far.

NITROGEN METABOLISM *Beggiatoa* and *Thioploca* spp. show considerable versatility in utilizing nitrogen compounds, either as nitrogen source for growth or, in the case of nitrate, as electron acceptor for respiration. All in all, several kinds of nitrogen utilization can be distinguished.

Heterotrophic freshwater *Beggiatoa* spp. assimilate various nitrogen components for growth. *Beggiatoa alba* strains can use nitrate, nitrite, ammonia and casamino acids as sole nitrogen source (Mezzino et al., 1984), and for strain B18LD, the list also includes urea, aspartate, asparagine, alanine and thiourea (Vargas and Strohl, 1985a). *Beggiatoa alba* B18LD assim-

ilates ammonia by the glutamine synthetase–glutamate synthase pathway (Vargas and Strohl, 1985a). Nitrate could not be used as electron acceptor for growth with sulfide oxidation; it allowed a limited degree of acetate oxidation but was not sufficient to sustain growth as the sole electron acceptor. The enzyme activity was associated with the soluble fraction, not with the cell membranes, and produced ammonia as the waste product. On the basis of its cellular localization and biochemical properties, the nitrate reductase of *Beggiatoa alba* appeared to be an assimilatory nitrate reductase (Vargas and Strohl, 1985b).

Nitrogenase activity in *Beggiatoa alba* was strongly regulated by nitrogen compounds. Nitrate and nitrite additions to the growth medium prevented induction of nitrogenase. In vivo nitrogenase activity was only inhibited by ammonia and urea (Polman and Larkin, 1988). Similarly, for the heterotrophic freshwater strain OH-75-2a and for several other strains isolated from a warm freshwater spring (Nelson and Castenholz, 1981a; Nelson and Castenholz, 1981b), and also for the autotrophic marine strains MS-81-1c and MS-81-6, nitrogenase was repressed by nitrate and ammonia in the growth medium (Nelson et al., 1982b). Thus, *Beggiatoa* spp. can contribute to total nitrogen fixation in their natural habitats, including cyanobacterial mats, intertidal sulfureta, and sediments.

The large *Beggiatoa* and *Thioploca* species that accumulate nitrate intracellularly use it most likely as a respiratory electron acceptor for sulfur oxidation (Fig. 14). The large marine *Beggiatoa* sp. from Monterey Canyon, with an intracellular nitrate content of ca. 160 mM, showed the highest level of nitrate reductase in comparison to other strains. Nitrate reductase activity was predominantly found in the particulate fraction, indicating a membrane-bound location within the respiratory chain (McHatton et al., 1996).

A respiratory role for nitrate is also strongly supported for large *Thioploca* spp. When freshly collected filaments of large marine *Thioploca* spp. were incubated with 15N-labeled nitrate, the *Thioploca* cells accumulated labeled nitrate in their vacuoles and reduced it mainly to ammonia. A small amount of dinitrogen was produced, but in this contaminated natural assemblage it cannot be assigned with assurance to the metabolism of *Thioploca* (Otte et al., 1999). Owing to nitrate ammonification by *Thioploca*, ammonia accumulates at high rates in *Thioploca*-harboring sediment surface layers (Thamdrup and Canfield, 1996). The ammonia produced can be readily reassimilated by other bacteria or reoxidized to nitrate by other chemoautotrophs at the sediment water interface. Thus, nitrogen com-

pounds are not lost from the ecosystem via denitrification (Farias et al., 1996; Farias, 1998).

SULFUR METABOLISM The formation of intracellular sulfur globules by oxidation of reduced sulfur sources is one of the basic, defining features of the genera *Beggiatoa* and *Thioploca*. The physiological roles of sulfide oxidation and sulfur accumulation are complex and diverge between different physiological types of *Beggiatoa* spp (Fig. 15). In autotrophic *Beggiatoa*, sulfide is a source of energy and electrons for carbon fixation and growth. Autotrophic sulfur oxidation was first studied in *Beggiatoa* str. MS-81-6 growing in sulfide gradient cultures, where *Beggiatoa* filaments grew as a defined band in a slush soft agar column at the sulfide-oxygen interface (Nelson and Jannasch, 1983). The *Beggiatoa* filaments in the gradient culture migrated over time and their position remained at the sulfide/oxygen interface. Their growth depended on availability of both compounds, oxygen and sulfide, in opposed overlapping gradients (Nelson and Jannasch, 1983; Nelson et al., 1986a). *Beggiatoa* str. MS-81-6 showed considerable flexibility in adjusting the oxidation pathways of sulfide during different

growth stages. Sulfide oxidation could lead to the stage of elemental sulfur, which maximized hydrogen sulfide removal when this compound was overabundant. Alternatively, sulfide could be completely oxidized to sulfate, which used sulfide most efficiently as electron donor when the supply was limited (Nelson et al., 1986a). Sulfide is biologically oxidized at a rate that is roughly three orders of magnitude faster than the competing chemical oxidation, with half-life times of a few seconds in the oxygen-sulfide transition zone (Nelson et al., 1986a). In comparison to other autotrophic sulfur-oxidizing bacteria, both marine autotrophic *Beggiatoa* strains tested have high molar growth yields (8 g/mol for *Beggiatoa* str. MS-81-6, and 16 g/mol for MS-81-1c) on sulfide in gradient cultures (Nelson et al., 1986a; Hagen and Nelson, 1997).

Physiological differences between the obligately autotrophic strain (MS-81-1c) and the facultatively autotrophic strain (MS-81-6) are apparent in different enzyme systems for sulfur oxidation (Hagen and Nelson, 1997). *Beggiatoa* strain MS-81-1c uses APS reductase (adenosine 5'-phosphosulfate reductase; located in the cytosol) in the AMP-dependent oxidation of sulfite to APS. In a second step catalyzed by the enzyme

ATP sulfurylase, the pyrophosphate-dependent substrate-level phosphorylation of APS produces ATP and sulfate:

Both enzymes are highly active regardless of the sulfur source (H_2S gradient, thiosulfate, or thiosulfate with acetate). Substrate-level phosphorylation during sulfur oxidation opens a new source of energy for this *Beggiatoa* strain, in contrast to other *Beggiatoa* strains that appear to lack this pathway and depend on respiratory sulfur oxidation. *Beggiatoa* strain MS-81-6 completely lacks APS reductase activity. The activity of the ATP sulfurylase is two orders of magnitude lower than in strain MS-81-1c, and in the typical range for assimilatory ATP sulfurylases. An assimilatory role for the ATP sulfurylase is supported by the ability of strain MS-81-6 to grow with acetate on sulfate as the only sulfur source (Nelson and Jannasch, 1983).

An AMP-independent, apparently membrane-associated, sulfite:acceptor oxidoreductase system represents a second sulfur oxidation pathway, which is found in *Beggiatoa* strains MS-81-1c, MS-81-6, and OH-75-2a. Since these sulfite oxidases are localized in the cell membrane, it is very likely that they are integrated with the respiratory chain and use cytochrome *c* as electron acceptor. In strain MS-81-1c, sulfite:acceptor oxidoreductase is upregulated in the presence of H_2S and is at least three times higher than in strain MS-81-6. The different rates of respiratory sulfur oxidation, and additional substrate phosphorylation coupled to sulfite oxidation by the APS reductase system in strain MS-81-1c, probably contribute to the differences in molar growth yield between strains MS-81-1c and MS-81-6 (Hagen and Nelson, 1997).

Interestingly, the heterotrophic freshwater *Beggiatoa* strain OH-75-2a showed a similar spectrum of sulfur-oxidizing enzymes as the facultative autotroph. AMP-independent sulfite:acceptor oxidoreductase was present and active in a similar range as in strain MS-81-6, allowing in principle the energy-gaining oxidation of sulfur compounds. However, the activities of ATP sulfurylase were an order of magnitude lower than in strain MS-81-6, and three orders of magnitude lower than the ATP sulfurylase in strain MS-81-1c; thus, the ATP sulfurylase appears to be assimilatory rather than dissimilatory (Hagen and Nelson, 1997).

The sulfur-oxidizing enzyme system of the facultatively autotrophic freshwater *Beggiatoa* strain D-402 shared important features with strains MS-81-6 and OH-75-2a. AMP-dependent

APS reductase was absent; sulfur-oxidizing enzymes that are not involved in substrate-level phosphorylation (sulfite:cytochrome *c* oxidoreductase and thiosulfate:ferricyanide oxidoreductase) were active and were upregulated under autotrophic cultivation conditions with thiosulfate as sulfur source (Grabovich et al., 1998; Grabovich et al., 2001; Patriitskaya et al., 2001). The unusually high activities of RuBPC/O and of sulfur-oxidizing enzymes in strain D-402 could be connected to its high growth yield (12.2 g/mol of oxidized thiosulfate). Direct comparisons of *Beggiatoa* strain D-402, MS-81-1c, MS-81-6 and OH-75-2a with identical culture conditions, sulfur sources, and enzyme assays are necessary to determine the physiological diversity and activity of sulfur-oxidizing enzymes in marine and freshwater *Beggiatoa*.

Sulfur metabolism in other heterotrophic *Beggiatoa* strains differs considerably from sulfur oxidation in autotrophic strains. The heterotrophic *Beggiatoa* strain OH-75-2a was quantitatively studied for sulfide and thiosulfate oxidation effects. Here, sulfide oxidation did not result in additional biomass yield beyond that obtained from oxidation of organic carbon sources; in other words, a mixotrophic growth enhancement by sulfide oxidation that was often proposed by nonquantitative studies of *Beggiatoa* spp. was not found (Nelson and Castenholz, 1981b). The oxidation of sulfur compounds had other functions in this *Beggiatoa* strain. Thiosulfate additions and catalase additions reduced the lag time in the growth of new *Beggiatoa* cultures, suggesting that thiosulfate acts like catalase as a detoxifying agent and electron acceptor for the oxidation of peroxides. Sulfur granules could also serve as an electron acceptor reserve that allows a rudimentary anaerobic respiration with sulfur. *Beggiatoa* str. OH-75-2a used sulfur globules that were accumulated during aerobic thiosulfate oxidation, to sustain anaerobic metabolism and growth during several days of anoxia (Nelson and Castenholz, 1981b). Reduction of sulfur globules to sulfide, coupled to de novo synthesis of cell material, was also found in *Beggiatoa alba* B18LD during anoxic incubation (Schmidt et al., 1987). This mechanism could occur in numerous, so far untested strains of heterotrophic, freshwater *Beggiatoa* spp., and would help the filaments to survive periods of anoxia in their natural interface habitat (Schmidt et al., 1987). However, *Beggiatoa alba* B18LD remains dependent on oxygen for sulfide (and acetate) oxidation. As in autotrophic *Beggiatoa* spp., sulfide oxidation required oxygen as electron acceptor. *Beggiatoa alba* B18LD harbors *c*-type cytochromes that could play a role in respiratory sulfur oxidation (Cannon et al., 1979). There is circumstantial evidence that acetate and sulfide

oxidation compete for oxygen; the addition of acetate and other carbon sources inhibited sulfide oxidation and accumulation of intracellular sulfur globules in *Beggiatoa alba* B18LD considerably (Schmidt et al., 1987). The oxidation of sulfur compounds in *Beggiatoa alba* B18LD stopped essentially at the stage of the elemental sulfur globules. Under a wide range of test conditions, *Beggiatoa alba* B18LD filaments harboring sulfur globules did not release significant amounts of soluble sulfur oxidation products into the surrounding medium (Schmidt et al., 1987).

Oxidation of reduced sulfur compounds is linked to nitrate reduction in large, marine *Beggiatoa* and *Thioploca* spp. Sulfide oxidation and ammonia production rates in marine *Thioploca* samples showed a stoichiometric ratio of ca. 2, suggesting that nitrate reduction to ammonia was accompanied by concomitant sulfide oxidation to sulfur (stoichiometric ratio 1 : 4) and sulfate (ratio 1 : 1); no sulfur intermediates were detected. Apparently, sulfide is oxidized first to elemental sulfur, which acts as an intracellular electron donor reservoir, and then in a second step, to sulfate. In the absence of sulfide, the ratio of ammonia production (requiring 8 electrons per ammonia) and sulfate production (yielding 6 electrons per sulfate) is close to the predicted stoichiometric ratio of 1.3 : 1 (Otte et al., 1999). A similar sulfur oxidation pathway could exist in large, marine *Beggiatoa* spp. which resemble large marine *Thioploca* spp. in vacuolation and nitrate storage capacity (McHatton et al., 1996). In large marine *Beggiatoa* spp. from the Guaymas Basin (30 μ m filament diameter, sample 1615), diverse *c*-type cytochromes were found whose hemes have appropriate oxidation-reduction midpoint potentials for respiratory sulfide oxidation (Prince et al., 1988).

Phylogeny and Taxonomy

As a morphologically conspicuous genus, *Beggiatoa* was at an early stage included in comparative 5S rRNA analysis (Stahl et al., 1987) and identified as a member of the γ -Proteobacteria. By 16S rRNA sequence analysis, *Beggiatoa* and *Thioploca* spp. form a deep branch within the γ -Proteobacteria, a subdivision of the Proteobacteria that harbors numerous free-living and symbiotic types of sulfur-oxidizing bacteria. The filamentous sulfur oxidizer *Thiothrix* is a member of the γ -proteobacterial subdivision, but not related to *Beggiatoa* or *Thioploca* (Teske et al., 1995; Howarth et al., 1999). The large, vacuolated, marine *Beggiatoa* and *Thioploca* species form a well-defined branch that is separated from the smaller, autotrophic and heterotrophic

Beggiatoa spp. (Teske et al., 1995; Teske et al., 1999; Ahmad, 1999a; Ahmad et al., 1999b; Mussmann et al., 2003). This branch also includes the genus and species *Thiomargarita namibiensis*, a nonmotile vacuolated sulfide-oxidizing bacterium that relies on its intracellular nitrate storage capacity for survival; *Thiomargarita* holds the current record among prokaryotes for cell size by volume (Schulz et al., 1999). On the basis of 16S rRNA data, considerable phylogenetic depth separates the physiologically divergent, cultured members of the genus *Beggiatoa*, the obligately or facultatively autotrophic marine strains (strains MS-81-1c and MS-81-6), the heterotrophic freshwater *Beggiatoa* strains (str. OH-75-2a, *Beggiatoa alba* B18LD (T), B15LD, and *Beggiatoa* str. 1401-13), and the mutually related, large marine *Beggiatoa* and *Thioploca* strains (Fig. 16). As discussed in the Identification section, the 16S rRNA data will be important for a possible future restructuring of the genera *Beggiatoa* and *Thioploca*.

In parallel to 16S rRNA sequencing, 16S rRNA probes have been designed for fluorescence in situ hybridization (FISH) and discrimination of different *Beggiatoa* and *Thioploca* species and strains (Teske et al., 1995; Teske et al., 1999; Ahmad et al., 1999b; Kojima et al., 2003; Mussmann et al., 2003). Using FISH probes, community level associations and interactions of *Beggiatoa*, *Thioploca*, and sulfate-reducing bacteria could be visualized in detail (Fukui et al., 1999).

Besides 16S rRNA sequencing, little work has been done on the molecular characterization of *Beggiatoa* and *Thioploca*. The molecular mass of the *Beggiatoa alba* genome has been determined by CoT analysis as 2.02×10^9 , which corresponds to 3.03×10^6 base pairs, similar to *E. coli* (Genthner et al., 1985). The G+C content for the *Beggiatoa alba* strains B18LD, B15LD and B25RD was determined to be 40–42.7 mol%. The phenotypically similar strain L1401-15 had a different G+C content of 51.7 mol% and appeared to be genetically distinct (Mezzino et al., 1984). The three former *Beggiatoa alba* strains contained plasmids with molecular masses of 12.3–12.8 $\times 10^6$ (or 18.9–19.7 kb) with no described function (Minges et al., 1983). Independent analyses (D. C. Nelson, unpublished observation) determined the following mol% G+C values: B18LD (37.1%), B25RD (35.5%), and OH-75-2a (38.5%). *Beggiatoa alba* was included in a polymerase chain reaction (PCR) survey for dissimilatory sulfite reductase, one of the key enzymes of prokaryotic dissimilatory sulfite and sulfate reduction, and reacted negatively (Wagner et al., 1998).

DNA hybridizations determined the presence of dissimilatory ATP sulfurylase genes in dif-

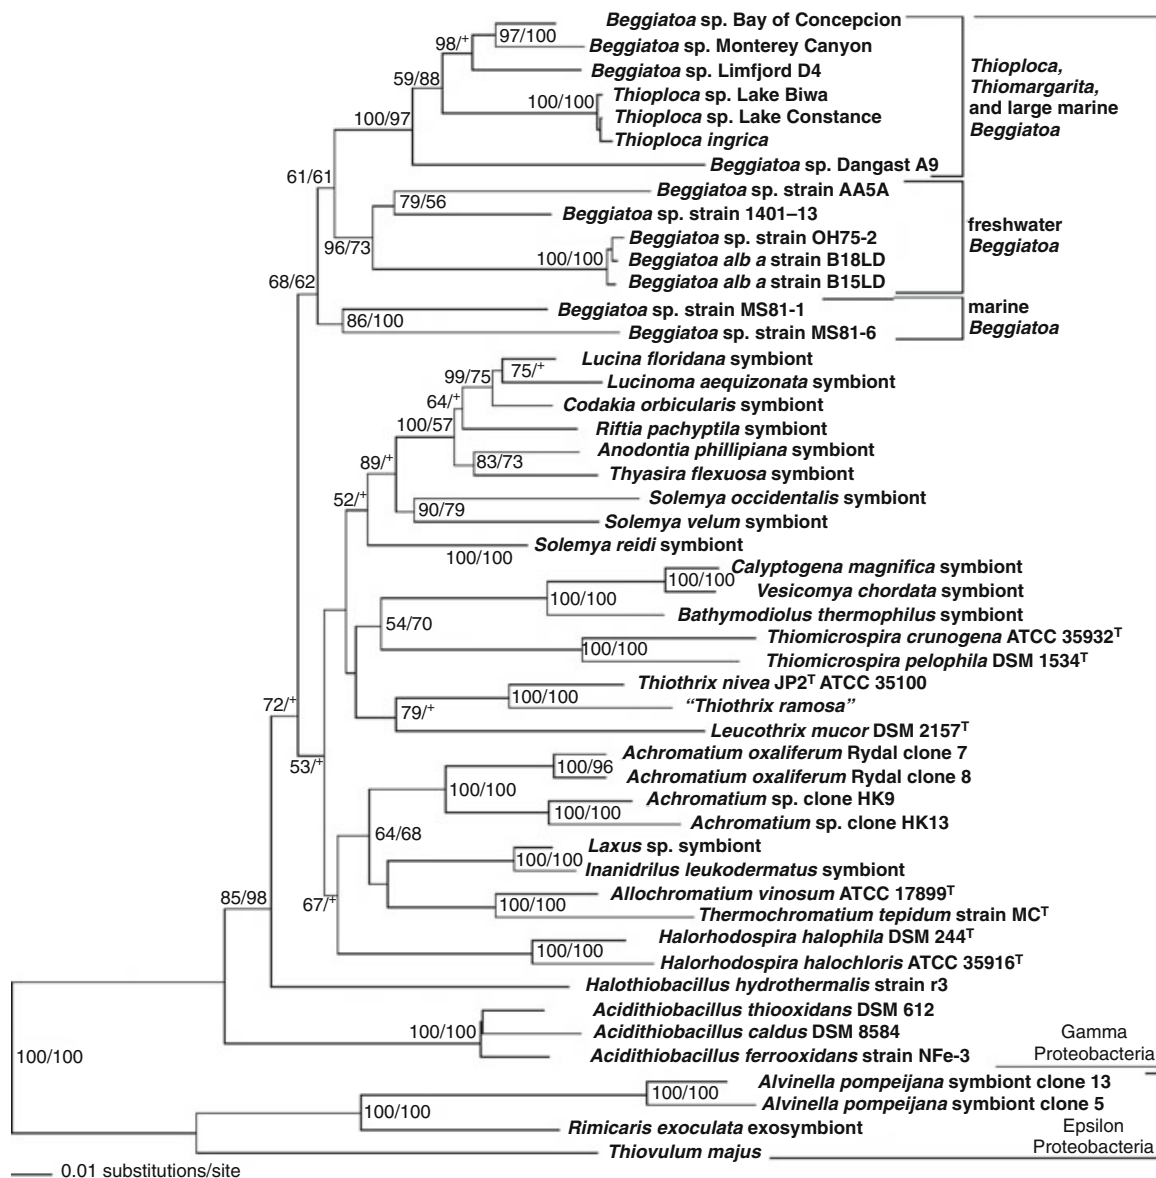

Fig. 16. Phylogeny of the genera *Beggiatoa*, *Thioploca* and *Thiomargarita*, based on A) nearly complete 16S rDNA sequences (*E. coli* positions 28–1487) and B) on partial sequences (*E. coli* positions 341–941), including partial sequences of *Thioploca chileae*, *T. araucae* and *Thiomargarita namibiensis*. Bootstrap values of 1000 replicates (minimum evolution/parsimony) are indicated at nodes with more than 50% bootstrap support.

ferent *Beggiatoa* strains. The gene probe was a fragment of the ATP sulfurylase gene of the autotrophic, sulfur-oxidizing endosymbiont of the hydrothermal vent tube worm *Riftia pachyptila*; the endosymbiont utilizes ATP sulfurylase and APS reductase in dissimilatory sulfur metabolism. DNA of the autotrophic strain MS-81-1c hybridized positively, whereas DNA of the facultatively heterotrophic strain MS-81-6 and of the heterotrophic strain OH-75-2a hybridized negatively, indicating that the latter two strains harbor assimilatory, not dissimilatory ATP sulfurylases (Laue and Nelson, 1994). In general, the

paucity of genetic studies leaves a wide-open field of highly rewarding research, for example a genetic analysis of enzymatic pathways and regulation of the environmentally significant sulfur oxidation pathways.

Ecology of *Beggiatoa*

Beggiatoa and *Thioploca* mats employ different ecophysiological strategies to oxidize sulfide efficiently and to compete with the chemical oxida-

bottom agar was exhausted (Nelson et al., 1986b).

A phobic response to high oxygen concentrations seems to be a driving force in establishing well-defined *Beggiatoa* mats. *Beggiatoa* filaments on a sediment surface adjust their position to short-term fluctuations in the sulfide and oxygen supply; they avoid high oxygen concentrations by contracting into the diffusive boundary layer directly at the sediment surface, and expand after the oxygen stress has passed (Møller et al., 1985). Oxidative damage to essential enzymes by peroxide formation is one of the presumed reasons for the general oxygen sensitivity of *Beggiatoa* spp.; for example, H_2O_2 exposure inhibited fumarate hydratase, an essential TCA cycle enzyme, in the heterotrophically growing *Beggiatoa* freshwater strain D-405 (Grabovich et al., 1993). A cytochemical study using 3,3'-diaminobenzidine (DAB) showed the location of products of partial oxygen reduction, hydrogen peroxide and the superoxide radical. H_2O_2 accumulated primarily in the periplasmic space, and on the outer surface of the cell wall; superoxide radical formation took place mostly at the cytoplasmic membrane with lesser amounts in the periplasmic space and on the outer cell wall surface (Chekanova and Dubinina, 1990). The rate of peroxide production was proportional to oxygen consumption during respiration; when electron donors (pyruvate, catalase, thiosulfate) were added to the culture medium, they acted as antioxidants which stabilized growth and increased the cell yields (Dubinina et al., 1990).

Beggiatoa can occur in association with other filamentous bacteria and form complex microbial mats, for example in benthic cyanobacterial mats (Garcia-Pichel et al., 1994). Cyanobacterial mats form a gradient habitat with suitable interface conditions for *Beggiatoa* (Jørgensen, 1982). At daytime, the upper layers of cyanobacterial mats are supersaturated with oxygen as a consequence of cyanobacterial photosynthesis. At night, oxygen production ceases and sulfide produced by sulfate reduction moves up towards the mat surface (Jørgensen et al., 1979; Jørgensen et al., 1983b). If this interface remains outside of the photic zone during the day, photosynthetic sulfur-oxidizing bacteria are excluded, and *Beggiatoa* spp. colonize a cyanobacterial mat and grow along the oxic/anoxic interface. The hypersaline cyanobacterial mats of Guerrero Negro are a good example (Jørgensen and DesMarais, 1986). Migrating *Beggiatoa* filaments closely follow the diel up-and-down movement of the oxygen/sulfide interface by ca. 1 mm, but always maintain a safe distance from fully oxic conditions (Garcia-Pichel et al., 1994). Their gliding speed of 1–2.6 μm per sec surpassed the speed of cyanobacteria in the same mat, which can retreat

into the mat matrix to avoid excessive irradiation during the day (Garcia-Pichel et al., 1994). A special case of cyanobacterial mats with a significant *Beggiatoa* component are the horizontally migrating, sulfide-producing and sulfide-oxidizing mats dominated by the gliding filamentous cyanobacterium *Phormidium corallyticum*. These mats are the causative agent of black-band coral disease, by overgrowing and completely degrading coral tissue (Carlton and Richardson, 1995).

The migrations of *Beggiatoa* filaments in microbial mats and cyanobacterially dominated sediments is not only regulated by the combined effects of oxygen and sulfide but is, in parallel, controlled by light. Experiments with *Beggiatoa* cultures from a warm freshwater spring (Hunter Spring) have shown a statistically significant photophobic response of individual *Beggiatoa* filaments, still detectable at low ambient light levels equivalent to ca. 2% of full summer sunlight intensity; filaments were most sensitive in the 400–500 nm spectrum that in nature is blocked out by cyanobacterial carotenoids. *Beggiatoa* filaments in field material maintained in the laboratory enrichments retreated into the sediment after short illumination, and returned to the sediment surface after several hours of darkness (Nelson and Castenholz, 1982a).

Large marine *Beggiatoa* spp. occupy a slightly different ecological niche than the small marine strains that were discussed previously; they are not tied to thin oxygen-sulfide interfaces but can tolerate fluctuating sulfide and oxidant levels. The extraordinary thickness of these mats (up to several cm), or their growth as virtual monocultures that can be harvested with a vacuum-cleaner-like device (Jannasch et al., 1989b; Nelson et al., 1989), rules out a growth pattern in the micrometer-thin interface of stabilized sulfide/oxygen gradients. Dense *Beggiatoa* mats growing on hydrothermally active sediments of the Guaymas Basin are exposed to irregularly fluctuating pulses of oxygenated seawater and sulfide from the sediment (Gundersen et al., 1992). This continuous mixing of sulfide and seawater is sustaining mats of extraordinary thickness. The ecophysiological flexibility of large *Beggiatoa* spp. is enhanced by their ability to accumulate nitrate intracellularly and to use it as electron acceptor for sulfide oxidation. All large *Beggiatoa* and *Thioploca* spp. studied so far accumulate nitrate from the 10–100 μM range in surrounding seawater to ca. 100 mM intracellular concentration (McHatton et al., 1996). For the Guaymas *Beggiatoa*, the intracellular nitrate accumulation is in the range of 50–100 mM (A. Teske, unpublished observation). These concentrations would not be possible with oxygen that reaches saturation around 250 μM . With this storage capacity,

Beggiatoa spp. can grow for several hours without external supply of oxidant (McHatton et al., 1996). The most likely nitrate reduction product, based on parallel results with *Thioploca* spp., is ammonia, not dinitrogen (Otte et al., 1999).

Large, nitrate-accumulating *Beggiatoa* spp. are not limited to hydrothermal vents and sulfide seeps but can be found on and within coastal, organic-rich, marine sediments as well (Jørgensen, 1977; Musmann et al., 2003). Nitrate-accumulating *Beggiatoa* spp. occur within anoxic, near-surface sediments where they oxidize sulfide produced in situ by sulfate reduction. Their nitrate-storing ability allows them to survive within the sediment, down to 2–4 cm depth. Thus, *Beggiatoa* spp. can occur within the sediment and do not always form conspicuous mats on the sediment surface (Musmann et al., 2003); in both cases, they play an important role in the nitrogen and sulfur cycle of marine sediments. A seasonal study of *Beggiatoa* mats in the Bay of Concepción showed how these seasonally developing *Beggiatoa* mats transform the bottom sediment from an ammonia sink to an ammonia source (Graco et al., 2001). Summer hypoxia at the bottom of the Bay favors the development of *Beggiatoa* spp. mats which reduce nitrate and release ammonia from the sediment into the water column, thus augmenting the traditional ammonia flux from anaerobic decomposition of organic matter. In parallel, sulfide buildup in the sediment porewater, due to increased organic matter degradation by sulfate reduction, inhibits nitrification and denitrification in the sediment and favors nitrate reduction by ammonia-producing *Beggiatoa* spp. (Graco et al., 2001). Similar findings have been reported for mats of large, vacuolated *Beggiatoa* spp. in Tokyo Bay (Sayama, 2001) and for *Beggiatoa* mats in coastal Danish sediments (Risgaard-Petersen, 1995). The ammonia released to the water column forms a nitrogen source for pelagic production; nitrogen loss by denitrification is reduced. By increasing benthic-pelagic coupling of ammonia, *Beggiatoa* mats increase local productivity and contribute to coastal eutrophication.

Beggiatoa mats also play a significant role for the benthic-pelagic exchange of sulfur. Sulfate-reducing bacteria, the source of biogenic sulfide at the sediment-water interface, are attracted to the top of the anoxic zone by the increased nutrient supply; many strains can to a limited degree respire with oxygen (Cypionka, 2001). Sediments of a shallow brackish fjord (Limfjorden, Denmark) showed the link between sulfate reduction and *Beggiatoa* population density. Both sulfate reduction rates and *Beggiatoa* biomass density peaked at the sediment surface, in the upper cm. The sulfide uptake of these *Beggiatoa* spp. was so efficient that sulfide accumu-

lated only below the *Beggiatoa* layer, and the sulfide concentrations within the *Beggiatoa* layer remained near zero (Musmann et al., 2003). In this way, the *Beggiatoa* filaments act as a sulfide trap that prevents toxic sulfide from entering the water column; during this process they enrich the sulfur content of surface sediments, and allow resuspension and recycling of partially oxidized sulfur species in the water column (Grant and Bathmann, 1987).

Ecology of *Thioploca*

The ecology of *Thioploca* has been explored almost exclusively in the mats of large, nitrate-accumulating *Thioploca* species on the continental shelf off Chile and Peru (Fossing et al., 1995). The chemotactic motility that is characteristic for *Thioploca* was investigated with Chilean *Thioploca* species, and also the geochemical framework in the following discussion refers to the Chilean data, which give a multifaceted picture of the ecology of marine, nitrate-respiring *Thioploca*. That does not mean that other *Thioploca* spp. always behave similarly; the study of freshwater *Thioploca* spp. with modern approaches is just beginning (Kojima et al., 2003) and may yield surprises in the future.

The ecological niche of *Thioploca* is characteristically different from *Beggiatoa*. *Thioploca* is a gradient organism with a twist. *Thioploca* filaments can move up and down in their gelatinous sheaths that are embedded in the surface sediment. Thus, they can adjust their position in redox gradients by retreating into the sediment, or emerging through the benthic boundary layer and take up nitrate from the water column (Hüttel et al., 1996). Finely tuned phobic responses to high sulfide and high oxygen concentrations, and a strong attraction to nitrate that even overrides oxygen aversion to some degree, determine this complex behavior of *Thioploca*. After nitrate addition to seawater overlying a *Thioploca* mat, *Thioploca* filaments emerge partially from their sediment-embedded sheaths and sway in the current like white hair while taking up nitrate from the water (Hüttel et al., 1996). Subsequently, *Thioploca* filaments can retreat (at a speed of 3–5 mm h⁻¹) into the sediment and use their stored nitrate for sulfide oxidation. In this way, *Thioploca* can bridge and exploit spatially separated pools of sediment sulfide and seawater nitrate and modify the “holding your breath” strategy of nitrate accumulation and respiration of large, marine *Beggiatoa* spp. with limited motility. For large *Thioploca* spp. from the Chilean continental shelf, the intracellular nitrate and sulfur reserves allow a turnover time of 8–10 days (Otte et al., 1999). For longer-term survival, *Thioploca*

spp. require just the right balance of anoxia (nitrate, no oxygen) in the bottom water and sulfate-reducing activity in the sediment, in the sense that sulfide production must not overwhelm the sulfur-oxidizing capability of *Thioploca*. *Thioploca* is in fact very sensitive to changes in its environment. Temporary bottom water oxygenation during the southern winter depressed *Thioploca* populations significantly (Schulz et al., 2000). Also, local high sulfate reduction rates and high levels of free sulfide in the sediment changed the environmental balance from *Thioploca* mats to sheathless, *Beggiatoa*-like sulfur oxidizers on the sediment surface (Schulz et al., 2000).

This survival strategy of *Thioploca* spp. contrasts with the ecophysiology of its recently discovered relative *Thiomargarita namibiensis*. This immotile, giant sulfur oxidizer is the largest known prokaryote by volume; it relies completely on its enormous storage capacity for sulfur and nitrate to carry it through irregular natural fluctuations of sulfide and nitrate concentration in its sedimentary habitat (Schulz et al., 1999; Schulz, 2002a). In contrast to the very oxygen-sensitive Chilean *Thioploca* spp., *Thiomargarita namibiensis* tolerates prolonged oxygen exposure and, in addition to nitrate, appears to be able to use oxygen for sulfide oxidation if acetate is provided. This respiratory flexibility probably helps *Thiomargarita namibiensis* to tolerate irregular fluctuations of sulfide, nitrate and oxygen during resuspension episodes in its natural habitat (Schulz and DeBeer, 2002b).

The structure of the Chilean *Thioploca* mats is conducive to the microbial lifestyle of bridging sulfide and nitrate pools. The densest *Thioploca* mat matrix of randomly orientated filaments and

Fig. 17. A flume experiment with freshly harvested *Thioploca* mat from the Chilean continental shelf simulates in situ conditions where nitrate-accumulating *Thioploca* filaments extend 1–3 mm in a vertical direction above the sediment surface and through the diffusive boundary layer into the nitrate-rich current. From Hüttel et al. (1996).

bundles is found in the uppermost centimeter layer, while predominantly vertically orientated, less densely packed *Thioploca* bundles reach a depth of generally 4–8 cm, or maximally 10–15 cm (Schulz et al., 1996). The surface layer of the mat is generally well supplied with nitrate; it can penetrate several centimeters into the hydraulically conductive, porous and soft *Thioploca* mats sediments (Hüttel et al., 1996). The upper 1–5 cm of the sediment also show the highest sulfate reduction rates, up to 1500 nmol cm⁻³ d⁻¹, which are extremely high rates for marine sediments. Nevertheless, efficient in situ reoxidation of sulfide keeps the sulfide concentrations in the *Thioploca* mat sediments low, mostly in the range of 5–50 μm, and sulfate concentrations were never depleted below bottom water concentrations (Thamdrup and Canfield, 1996; Ferdelman et al., 1997). *Thioploca* mats contribute significantly to this in situ anaerobic sulfide reoxidation; different data sets and experimental approaches indicated a *Thioploca* contribution of 16–35%, or 25–91%, to the total in-situ sulfide oxidation in the sediment (Ferdelman et al., 1997; Otte et al., 1999).

This highly efficient internal sulfur recycling could benefit from the close spatial association between sulfate-reducing and sulfur-oxidizing bacteria in *Thioploca* mats. *Thioploca* biomass and cultivable most probable numbers (MPNs) of sulfate-reducing bacteria both peak in the surface layer of the mat (A. Teske, unpublished results). Filamentous sulfate reducers of the genus *Desulfonema* grow on and within the *Thioploca* sheaths, suggesting a complete cycle

Fig. 18. Diagram showing how chemotactic responses and the concentration of an internal trigger may control vertical shuttling in *Thioploca* spp. The shading of the trichomes reflects the concentrations of the trigger (e.g., nitrate) in the filaments. The arrows indicate the chemotactic attraction of and the movement toward sulfide and nitrate, respectively. The minus signs indicate phobic responses to high concentrations of oxygen or sulfide. From Hüttel et al. (1996).

of sulfate reduction and reoxidation within a single *Thioploca* bundle (Fukui et al., 1999).

The high intracellular concentrations of sulfur and nitrate are correlated to the position and activity of *Thioploca* filaments in the gradient. "Deep" *Thioploca* filaments tend to consume their nitrate content for sulfide oxidation and build up sulfur globules, and replenish their nitrate stocks at the surface where sulfur is consumed (Zopfi et al., 2001). The resulting elemental composition of these nitrate- and sulfur-loaded organisms has brought *Thioploca* another nickname, "gunpowder bacteria" (L. P. Nielsen, personal communication).

Owing to nitrate reduction and ammonification by *Thioploca*, ammonia accumulates at high rates in *Thioploca*-harboring sediment surface layers (Thamdrup and Canfield, 1996). The *Thioploca* mats turn the sediments from a denitrifying nitrogen sink into an ammonia-producing nitrogen source; ammonia fluxes across the sediment-water interface constitute a major, readily utilized and recycled nitrogen source for the water column over *Thioploca*-harboring areas (Farias et al., 1996; Farias, 1998). A seasonal pattern for ammonia flux is likely, as shown by seasonal studies of the *Thioploca* and *Beggiatoa* mats within and near the Bay of Concepción (Schulz et al., 2000; Graco et al., 2001). The mats develop in austral spring and summer during upwelling of oxygen-depleted, nitrate-rich equatorial subsurface water, and decay in winter during downwelling of well-oxygenated sub-Antarctic surface water (Schulz et al., 2000; Graco et al., 2001). During austral summer, the *Beggiatoa* mats inside the Bay of Concepción turn the sediment into a net ammonia source (Graco et al., 2001); similar seasonal patterns of ammonia flux are likely for the *Thioploca* mats that dominate the shelf sediments outside of the Bay.

Thus, the Chilean *Thioploca* and *Beggiatoa* mats shape the nitrogen and sulfur cycles of their environment to a considerable degree. In general, *Thioploca* and *Beggiatoa* mats play a double environmental role as sulfide scrubbers and detoxifiers, and as nitrate-reducing ammonia producers that play an essential role in benthic-pelagic coupling of nitrogen sources.

Acknowledgments. A. Teske was supported by an Independent Study Award from the Andrew W. Mellon Foundation at the Woods Hole Oceanographic Institution (WHOI contribution No. 10953). Sampling of Guaymas *Beggiatoa* spp. (Fig. 8a, b) was made possible by NSF grant Lexen- 9714195 to A. Teske. A portion of this work (DCN) was supported by National Science Foundation Grants OCE-9018198; IBN-9513962 and IBN-9983119.

The Family Halomonadaceae

DAVID R. ARAHAL AND ANTONIO VENTOSA

Introduction

The family Halomonadaceae, within the Gammaproteobacteria, consists mostly of marine and moderately halophilic microorganisms that are phenotypically rather diverse. Because of this apparent lack of a core of differential phenotypic traits, many of its current species were previously assigned to other genera such as *Deleya* (now extinct), *Alcaligenes*, *Pseudomonas*, *Halovibrio*, *Volcaniella*, etc. Reorganizations among these species started by the mid 1990s with the aid of 16S rRNA gene sequence comparison. In the meanwhile, new descriptions within the family Halomonadaceae have been reported, and the increasing number of species led some authors to review its phylogeny (Arahal et al., 2002a) and phenotypic features (Mata et al., 2002).

A Subcommittee on the Taxonomy of the Halomonadaceae, a member of the International Committee on Systematic of Prokaryotes, was constituted recently (Vreeland and Ventosa, 2003) and can be taken as a sign of the increasing interest in this group of organisms.

The genera *Halomonas* and *Chromohalobacter* have been largely studied as model organisms of halophilism. Some of their representatives are among the most halophilic bacteria (Ventosa et al., 1998) and are adapted to a wide range of saline concentrations, even wider than extreme halophiles. Another source of interest for the study of this group of organisms has been their potential in biotechnological applications. These include the production of compatible solutes, extracellular enzymes (adapted to saline stress), and exopolysaccharides among others.

Phylogeny

Five main phylogenetic studies have been conducted on the Halomonadaceae. In the first one (Franzmann et al., 1988), which was the basis for
